between the degree of distension of the bladder and the incidence of stress incontinence. The symptom was just as evident, sometimes more so, when the bladder was empty as at full distension, conforming with the clinical observation that the symptom was often quite troublesome soon after the bladder had been emptied voluntarily, in fact, owing to the pressure of the refractory phre at the beginning of distension it might be more so. As a minor way of combating the symptom he advised these patients to refrain from any sudden effort for a short period after micturition. In stress incontinence the control of micturition itself was normal and patients were able to stop the flow immediately they desired—an observation supporting the view that the lesion responsible for the stress incontinence was extrinsic to the bladder neck and the urethra. One group in which the jet escaped under pressure, and a second and smaller group, in which the urine leaked on any sort of effort, not necessarily an effort raising the intra-abdominal pressure, might be distinguished by the fact that in the first group the ordinary methods of repair proved adequate in the second group more specialized methods might be required.

A lateral cystogram gave much more information than an antero-posterior film, because the vesico-urethral junction was higher than the most dependent part of the bladder and could not be seen except in a lateral view. If changes in the contour of the bladder were to be seen, a weaker solution of sodium iodide than that usually employed was preferable, so the variations in the density of the shadow due to variations in the diameter of the bladder could then be picked out. In the descent of the bladder on straining noted in cases of cystocele and stress incontinence, the bladder appeared to descend as a whole. The vesico-urethral junction was situated far more in the mid-pelvis than was commonly supposed, this had a bearing on the operative repair of these cases. It was important to avoid any operative procedure which would approximate the bladder neck to the back of the symphysis. In many cases in which a repair operation had failed to relieve stress incontinence it would be found that this had been done—the urethra and anterior vaginal walls were closely applied to the back of the symphysis and had lost their normal curve. The good results sometimes obtained by a Goebbel-Stoeckel-Aldridge fascial sling operation were probably due to the fact that the operation ensured an upward rather than a forward displacement, but with great care it was possible to achieve this end by means of the more conventional techniques.

Finally, Mr Malpas showed a series of lateral radiographs taken during pregnancy and labour, mainly illustrating two points: the normal appearances and their variations from the non-pregnant condition and the significance of an "abdominal bladder" during the first stage of labour. In most cases of trial labour in which an "abdominal" bladder could be seen during the first stage, the bladder shadow being completely above the pelvic brim a Caesarean section would be necessary. In a normal labour the elevation of the bladder into the abdomen occurred quite late in the second stage, and even then was often incomplete in cases of easy labour. There was much to be said for combining the lateral radiograph with a lateral cystogram in the course of a trial labour.

Secondary Carcinoma of the Vulva

Prof T. N. A. JEFFCOATE reported a case of carcinoma of the vulva secondary to a primary growth in the breast. The patient was a nulliparous widow, aged 65, first seen in Oct., 1944, complaining of a small swelling in the groin, which she had had for the past six months. This had given rise to an occasional pricking sensation on walking. A little haematuria had been noted two months previously for two days. A radical mastectomy had been performed eight years before for carcinoma. The site of the scar showed no sign of recurrence either in the skin or in the axilla.

On examination the patient looked well, she was thin but did not show any obvious signs of loss of weight. Just lateral to the left pubic spine was a shallow ulcer covering an area of about that of a sixpence, with a serpiginous outline. Its base was rather hard but freely mobile on deep structures, the edges slightly raised. It had the appearance of umbilication. There was no enlargement of the glands in the groin. Beneath the skin of the left labium majus the position of Bartholin's glands a nodule

about the size of a pea could be felt. This was also mobile on deep structures, but was fixed to skin. The patient was admitted to hospital for investigations. The Wassermann was negative. A local excision was performed of the ulcer and nodule in view of the possibility of its being an intradermal carcinoma. Cystoscopy revealed an area on the right bladder wall the appearance of which was identical with that of the ulcer, about the same size and uniloculated. X-ray examination of the chest showed the lower lobe to be collapsed. Histological examination revealed that both lesions were probably metastatic growths, the primary being the previous breast carcinoma.

No further treatment was possible and the patient was kept under observation. Death occurred in 1945. The post-mortem examination showed widespread small metastatic growths, all secondary to the old breast carcinoma, the distribution was bizarre in the extreme, and involved parietal and visceral peritoneum, stomach muscle, the pancreas and even the appendix, both adrenals, the sternum, ribs, and vertebrae, both submaxillary glands, both ovaries, and the left Fallopian tube. It would seem that the secondaries appeared first in the mediastinal glands and were then disseminated in the blood stream. The extraordinary feature was that the vulva was chosen as the site of the first metastasis to attract attention, and that the patient's deterioration was so slow in view of the blood-borne spread.

Fatal Air Embolism in Pregnancy

Dr C. H. WALSH read a paper on fatal air embolism following vaginal insufflation during pregnancy.

The patient, a primigravida aged 17, was being treated by picric acid insufflations for leucorrhoea at about the thirtieth week of pregnancy. The first insufflation produced no discomfort, but the second a week later was followed by disaster. Insufflation was performed by a nurse with the patient lying in the left lateral position. Six or seven squeezes of the bulb were made. In a matter of seconds the patient became cyanosed, fought for breath, and became unconscious, dying in four or five minutes. Post-mortem examination revealed the uterus to be 30 to 31 weeks pregnant and to contain a normally developed foetus. The placenta was situated in the posterior upper segment and showed a small detachment at its lower border and stripping of the membranes down to the cervix, with a minute trace of picric acid powder in a maternal sinus. The inferior vena cava was ballooned with air and the right auricle markedly dilated and containing frothy blood. No other abnormality was observed in any other structure in the body. The immediate cause of death was pulmonary artery obstruction and right-sided heart failure due to air embolism.

It was pointed out that the insufflator delivered about 50 c.c.m. of air and powder, and in the average vagina, if the rubber cone made an airtight connexion with the introitus six or seven squeezes would blow in some 350 c.c.m. of air and powder, delivered at a pressure of at least 150 mm. Under these conditions even a small patent venule was capable of gobbling up air with fatal consequences. Some very interesting radiographs of intravasation of lipiodol occurring in the course of tubal patency tests were shown. The conclusions were mainly that the forcing of air under pressure into any cavity in the body might cause sudden death from air embolism. Pregnancy or a bleeding surface favoured air entry. Therefore it was suggested that vaginal insufflation was contraindicated in pregnancy or in the presence of bleeding from the uterus, and that tubal insufflation should be discarded in favour of lipiodol technique.

* Air embolism in pregnancy was the subject of a question and answer in the *Journal* of Dec. 1 (p. 793).

DUTCH PHARMACY UNDER THE NAZIS

Pharmaceutical conditions in Holland under the German occupation were reviewed in a lecture to members of the Pharmaceutical Society of Great Britain on Dec. 13 by Dr C. J. BLOK, chief pharmacist to the University and Municipal Hospitals, Amsterdam.

About 1943, said Dr Blok, many articles became so scarce that the General Office of Public Health found it necessary to limit the prescribing of the doctors. Cod-liver oil was only to be prescribed for tuberculosis, atropine only for Parkinsonism and as eyedrops, pilocarpine only for eyedrops, luminal only for epilepsy, ropan for serious stomach cases, dermatol only for epilepsy. After the Germans had robbed the safe of the Organon factories insulin also

be gradually established and the subscriptions of individuals and of associated libraries should enable the Royal Society of Medicine to continue the service without further help from the Rockefeller Foundation.

Preliminary work on detail of this scheme is in active progress. A conference will be convened by the Society at an early date to which institutions concerned in its original scheme will be invited to send representatives in order that the new plan may be laid before them.

LONDON VOLUNTARY HOSPITALS

INCREASING PUBLIC SUPPORT

King Edward's Hospital Fund for London has performed another service by producing an elaborate analysis of the finance and work of 167 voluntary hospitals in London in 1944.¹ The financial tables show the impressive volume of public support which these hospitals continued to command even in the year when London was subject to flying bombs and other war distractions and when in consequence the hospitals themselves had fewer beds occupied and fewer people coming to the out-patient departments. The subscriptions and donations rose by £80,000 over the amount for the previous year and reached a figure of £1,144,000. Contributory schemes brought in a further £733,000, again a considerable increase, but patients' payments were, of course, down.

The amount derived by the voluntary hospitals from the public authorities worked out at just over 30% of their total maintenance income. This amount differs widely as between different classes of hospitals and as between different hospitals in the same class. For the twelve teaching hospitals the total sum received from public authorities was £725,429, being 32.9% of income, and in the larger general hospitals without medical schools the percentage was higher, and in some of the special hospitals—the chest hospitals, for example—it rose to more than half the income. The total sum received by all the hospitals from public sources was £1,803,000, an increase of £373,000 on the year, the increase being due to grants under the E.M.S. scheme and towards the increase in nurses' salaries. The public is generous to the voluntary hospitals, but, on at any rate a superficial reading of these figures, erratic in its preferences. The teaching hospitals receive only 15% of their income from subscriptions and donations, but the larger non-teaching hospitals receive a considerably larger proportion—possibly a reflection of local pride. Of the teaching hospitals the favoured one in 1944 was the Royal Free, which received 45% of its income in the form of voluntary gifts, whereas St. Bartholomew's received only 11%; but St. Bartholomew's has a far larger income from invested property than any other hospital.

The total bed complement of these 167 hospitals at the end of 1944 was 23,377, but the number of beds open to patients was 17,721, and the average number occupied daily during the year was 10,405. One perplexing feature at first sight is the great difference between the average periods of residence of patients in different hospitals, even hospitals of the same class. In the teaching hospitals the average period varies from 21.4 days at the London to 12.9 days at St. Bartholomew's. It is a little difficult to see why the average period of residence should be twice as long at the Metropolitan Hospital as at St. John's, Lewisham, or twice as long at Hendon as at Purley. Among the children's hospitals the average stay of patients at Queen Elizabeth's is 21 days and at Paddington Green 11 days. No doubt the position is influenced by the number of patients who stay, particularly at certain hospitals, for very short periods. For example, at St. Bartholomew's 1,488 patients were in the wards for three days or less, as compared with 564 at Middlesex and 587 at Westminster, each of the hospitals having about the same total number of in-patients. Other factors may be the ratio of medical to surgical beds in different hospitals and the existence of convalescent-home facilities.

CARE OF CHILDREN UNDER FIVE

Recognizing as an "unattainable ideal for the present" a situation in which mothers of children under 2 years of age will be discouraged from going out to work, the Ministers of Health and of Education have in a recent circular, asked local authorities to make plans for adapting wartime nursing services to present needs and to submit these plans by the end of February. It is pointed out that for some time to come the need for women workers in certain vital industries may be as urgent as it was in wartime, and thus, with housing and shopping difficulties, makes it necessary that provision for the day-time care of children up to the age of 5 should continue, including some for the "under 2's," who are not admitted to nursery schools and classes. The methods to be adopted will rest with the local authorities, but the circular suggests a combination of the following: nursery schools, nursery classes, day nurseries, and schemes of day guardians, using maternity and child welfare centres on two or three afternoons a week as temporary crèches; organizing responsible women or older girls as volunteers to "sit in" at the homes of children while the parents go out together in the evening. Local authorities are asked to consider which wartime nurseries should continue to be run under maternity and child welfare powers; which should be taken over and run as nursery schools or nursery classes; and which should be closed. The cost of running wartime nurseries and wartime nursery classes will continue to be borne by the Exchequer until March 31. From that date such wartime nurseries as become nursery schools or nursery classes will attract the normal education grant from the Ministry of Education. Wartime nurseries continuing as day nurseries will receive a similar grant from the Ministry of Health. This grant will also be payable for registered day guardian schemes, afternoon crèches, and evening "sitters in."

MEDICAL FOUNDATION OF EPSOM COLLEGE

In spite of a long list of pensions, annuities, and scholarship, totalling over £13,000, awarded during 1945 the Royal Medical Foundation of Epsom College has to announce that owing to lack of funds many deserving applicants—medical men and women, and children of school age—remain unassisted. There is a waiting list of 28 applicants for pensions and 24 for annuities. The object of this Foundation is to help the families of less fortunate colleagues, and that this aid is given far and wide is seen from the following list for 1945:

General pensions	£
41 Foundation scholarships for boys educated, clothed, and maintained entirely free of cost	1,593
13 school trips for girls	676
15 exhibitions for boys	570
133 pensions and annuities of varying amounts	615
Grants towards education of 38 boys and girls	2,935
Grants to widows and spinsters	949
	322

When it is realized, however, that to maintain this assistance the Foundation has to rely upon the generosity of subscribers for over £10,000 a year, then the need for more and larger subscriptions is only too apparent. An appeal is therefore made for all who can to help the Foundation in its work in 1946. Subscribers may, if they wish, ask for their contribution to go to some particular beneficiary, and here it may be mentioned that the Sherman Bigg Fund enables the Foundation to make educational grants for those who cannot obtain scholarships. Subscriptions and donations for whatever aspect of the work may be sent to the Secretary, Epsom College Surrey.

A POLICE EXHIBITION IN 1946

A Police Exhibition is to be held at Brighton from June 4 to 22, when the Chief Constables' (Cities and Boroughs of England and Wales) Association will hold its fifteenth conference. The Brighton Corporation is lending part of the Municipal Art Galleries and Museum for the exhibition. Its objects will be to create a wider public interest in the preventive and detective aspects of crime, and to draw attention to the advances made in forensic science. Certain scientific and criminal exhibits will be shown privately in the Royal Pavilion. Invitations will be extended to members of the legal, medical, and scientific professions, magistrates, and police to visit this.

The Home Secretary has shown his interest in the exhibition, and the Home Office is helping in the preparatory work. The Commissioner of Police of the Metropolis is lending exhibits from the Museum at New Scotland Yard, and chief constables and directors of Home Office Forensic Science Laboratories are contributing from their collections. Offers to lend documents, records, and exhibits of historical, legal, criminal, or scientific interest will be welcomed, and correspondence should be addressed to the Chief Constable of

between the degree of distension of the bladder and the incidence of stress incontinence. The symptom was just as evident, sometimes more so, when the bladder was empty as at full distension, conforming with the clinical observation that the symptom was often quite troublesome soon after the bladder had been emptied voluntarily, in fact, owing to the pressure of the refractory phre at the beginning of distension it might be more so. As a minor way of combating the symptom he advised these patients to refrain from any sudden effort for a short period after micturition. In stress incontinence the control of micturition itself was normal and patients were able to stop the flow immediately they desired—an observation supporting the view that the lesion responsible for the stress incontinence was extrinsic to the bladder neck and the urethra. One group in which the jet escaped under pressure, and a second and smaller group, in which the urine leaked on any sort of effort, not necessarily an effort raising the intra-abdominal pressure, might be distinguished by the fact that in the first group the ordinary methods of repair proved adequate in the second group more specialized methods might be required.

A lateral cystogram gave much more information than an antero-posterior film, because the vesico-urethral junction was higher than the most dependent part of the bladder and could not be seen except in a lateral view. If changes in the contour of the bladder were to be seen, a weaker solution of sodium iodide than that usually employed was preferable, so the variations in the density of the shadow due to variations in the diameter of the bladder could then be picked out. In the descent of the bladder on straining noted in cases of cystocele and stress incontinence, the bladder appeared to descend as a whole. The vesico-urethral junction was situated far more in the mid-pelvis than was commonly supposed, this had a bearing on the operative repair of these cases. It was important to avoid any operative procedure which would approximate the bladder neck to the back of the symphysis. In many cases in which a repair operation had failed to relieve stress incontinence it would be found that this had been done—the urethra and anterior vaginal walls were closely applied to the back of the symphysis and had lost their normal curve. The good results sometimes obtained by a Goebbel-Stoeckel-Aldridge fascial sling operation were probably due to the fact that the operation ensured an upward rather than a forward displacement, but with great care it was possible to achieve this end by means of the more conventional techniques.

Finally, Mr Malpas showed a series of lateral radiographs taken during pregnancy and labour, mainly illustrating two points: the normal appearances and their variations from the non-pregnant condition and the significance of an "abdominal bladder" during the first stage of labour. In most cases of trial labour in which an "abdominal" bladder could be seen during the first stage, the bladder shadow being completely above the pelvic brim a Caesarean section would be necessary. In a normal labour the elevation of the bladder into the abdomen occurred quite late in the second stage, and even then was often incomplete in cases of easy labour. There was much to be said for combining the lateral radiograph with a lateral cystogram in the course of a trial labour.

Secondary Carcinoma of the Vulva

Prof T. N. A. JEFFCOATE reported a case of carcinoma of the vulva secondary to a primary growth in the breast. The patient was a nulliparous widow, aged 65, first seen in Oct., 1944, complaining of a small swelling in the groin, which she had had for the past six months. This had given rise to an occasional pricking sensation on walking. A little haematuria had been noted two months previously for two days. A radical mastectomy had been performed eight years before for carcinoma. The site of the scar showed no sign of recurrence either in the skin or in the axilla.

On examination the patient looked well, she was thin but did not show any obvious signs of loss of weight. Just lateral to the left pubic spine was a shallow ulcer covering an area of about that of a sixpence, with a serpiginous outline. Its base was rather hard but freely mobile on deep structures, the edges slightly raised. It had the appearance of umbilication. There was no enlargement of the glands in the groin. Beneath the skin of the left labium majus the position of Bartholin's glands a nodule

about the size of a pea could be felt. This was also mobile on deep structures, but was fixed to skin. The patient was admitted to hospital for investigations. The Wassermann was negative. A local excision was performed of the ulcer and nodule in view of the possibility of its being an intradermal carcinoma. Case report revealed an area on the right bladder wall the appearance of which was identical with that of the ulcer, about the same size and uniloculated. X-ray examination of the chest showed the lower lobe to be collapsed. Histological examination revealed that both lesions were probably metastatic growths, the primary being the previous breast carcinoma.

No further treatment was possible and the patient was kept under observation. Death occurred in 1945. The post-mortem examination showed widespread small metastatic growths, all secondary to the old breast carcinoma, the distribution was bizarre in the extreme, and involved parietal and visceral peritoneum, stomach muscle, the pancreas and even the appendix, both adrenals, the sternum, ribs, and vertebrae, both submaxillary glands, both ovaries, and the left Fallopian tube. It would seem that the secondaries appeared first in the mediastinal glands and were then disseminated in the blood stream. The extraordinary feature was that the vulva was chosen as the site of the first metastasis to attract attention, and that the patient's deterioration was so slow in view of the blood-borne spread.

Fatal Air Embolism in Pregnancy

Dr C. H. WALSH read a paper on fatal air embolism following vaginal insufflation during pregnancy.

The patient, a primigravida aged 17, was being treated by picric acid insufflations for leucorrhoea at about the thirtieth week of pregnancy. The first insufflation produced no discomfort, but the second a week later was followed by disaster. Insufflation was performed by a nurse with the patient lying in the left lateral position. Six or seven squeezes of the bulb were made. In a matter of seconds the patient became cyanosed, fought for breath, and became unconscious, dying in four or five minutes. Post-mortem examination revealed the uterus to be 30 to 31 weeks pregnant and to contain a normally developed foetus. The placenta was situated in the posterior upper segment and showed a small detachment at its lower border and stripping of the membranes down to the cervix, with a minute trace of picric acid powder in a maternal sinus. The inferior vena cava was ballooned with air and the right auricle markedly dilated and containing frothy blood. No other abnormality was observed in any other structure in the body. The immediate cause of death was pulmonary artery obstruction and right-sided heart failure due to air embolism.

It was pointed out that the insufflator delivered about 50 c.c.m. of air and powder, and in the average vagina, if the rubber cone made an airtight connexion with the introitus six or seven squeezes would blow in some 350 c.c.m. of air and powder, delivered at a pressure of at least 150 mm. Under these conditions even a small patent venule was capable of gobbling up air with fatal consequences. Some very interesting radiographs of intravasation of lipiodol occurring in the course of tubal patency tests were shown. The conclusions were mainly that the forcing of air under pressure into any cavity in the body might cause sudden death from air embolism. Pregnancy or a bleeding surface favoured air entry. Therefore it was suggested that vaginal insufflation was contraindicated in pregnancy or in the presence of bleeding from the uterus, and that tubal insufflation should be discarded in favour of lipiodol technique.

* Air embolism in pregnancy was the subject of a question and answer in the *Journal* of Dec. 1 (p. 793).

DUTCH PHARMACY UNDER THE NAZIS

Pharmaceutical conditions in Holland under the German occupation were reviewed in a lecture to members of the Pharmaceutical Society of Great Britain on Dec. 13 by Dr C. J. BLOK, chief pharmacist to the University and Municipal Hospitals, Amsterdam.

About 1943, said Dr Blok, many articles became so scarce that the General Office of Public Health found it necessary to limit the prescribing of the doctors. Cod-liver oil was only to be prescribed for tuberculosis, atropine only for Parkinsonism and as eyedrops, pilocarpine only for eyedrops, luminal only for epilepsy, ropan for serious stomach cases, dermatol only for epilepsy. After the Germans had robbed the safe of the Organon factories insulin also

THE SURGERY OF ARTERIAL DISEASE AND INJURY*

BY

Prof. J. PATERSON ROSS, M.S., F.R.C.S.

The early diagnosis and treatment of arterial injuries have been well described in the Medical Research Council's War Memorandum No. 13, but with the end of the war the problems of peripheral vascular disease will again become the more important, and therefore I intend to consider them first. I would like to make it clear from the start that they are not so intricate that only the specialist, working with a highly trained team at a special centre, can hope to understand them and to undertake the treatment of vascular disease. It should be the duty of those occupied in clinical research to correlate the results of their elaborate investigations with clinical methods of observation, so that the practitioner may be able to form a pretty accurate estimate of the nature and extent of the disease he has to treat. The surgical specialist should aim at simplification and standardization of technique, so that it may be easy or others to follow his lead, and thus the advances in surgical treatment may become widely known and practised.

Difficulties must arise when unusual features present themselves, and it is under such circumstances that the experience and judgment of the specialist are required in the selection of the patients who are likely to benefit from surgical treatment.

Raynaud's Disease

It is now customary to refer to any condition in which coldness and cyanosis of the digits occur on exposure to a moderately low temperature as the "Raynaud phenomenon." It may be seen in association with any form of obliterative or degenerative arteritis, it may be secondary to pressure by a cervical rib, or it may follow frost-bite or injury from the use of vibrating tools. It is unfortunate that Raynaud himself did not describe a single clinical entity, yet there is a clearly defined condition to which the term Raynaud's disease should be limited. It is characterized by colour changes in the digits produced by cold, occurring in attacks which show a rapid onset and recovery, and affecting the extremities symmetrically. The peripheral pulses are preserved, and if there is any loss of tissue it is never more than shallow ulceration close to the finger-tips; true gangrene is extremely rare. The disease is seen almost exclusively in the female sex—in fact, if a male patient presents a similar picture it is likely to be an early stage of obliterative arteritis and not Raynaud's disease.

A patient who suffers from Raynaud's disease in this country will be relieved of her symptoms by going to live in a warm climate, and even a change of occupation so as to avoid local exposure to cold will produce some improvement. We have not found emotion to be a common exciting cause of attacks; either is excessive sweating of the extremities at all frequent in our experience. For these and other reasons we follow Lewis's teaching that the disease is due to a local fault in the small arteries, and not to a central affection of the sympathetic nervous system. Furthermore, it must be pointed out that by the term "local fault" Lewis did not mean that even in mild Raynaud's disease there is some structural change in the vessels; he fault is an abnormal sensitivity to local cooling.

On the other hand, it can be shown that the more severe forms of Raynaud's disease are complicated by structural

changes in the arteries—obliterative arteritis and thrombosis—and this is the most important of the factors determining whether a patient is likely to benefit from surgical treatment. In the mildest form there are only colour changes in the digits, and the arteries are still able to dilate rapidly and completely as the attack passes off. There is an intermediate group of moderate severity complicated by shallow ulceration of the finger-tips, in which vasodilatation occurs more slowly and is incomplete. In the most severe group, which shows sclerodactyly or hypodermolihthiasis in addition to the other manifestations of Raynaud's disease, structural changes in the small arteries may prevent vasodilatation, so that the response to vasomotor inhibition or paralysis may be identical with that seen in advanced arteriosclerosis.

In Raynaud's disease the stimulus of cold almost obliterates the lumen of the digital arteries. After section of the vasomotor nerves their lumen is permanently increased, so that the same stimulus, while still reducing it greatly, does not arrest the circulation completely. The very different response to cold after sympathectomy in a person with normal vessels and in a patient with Raynaud's disease is further evidence in favour of the view that the vessels themselves are peculiarly susceptible to stimulation by cold.

It is clear, however, that unless sympathetic denervation is complete, vasodilatation will be inadequate, and the possibility of the obliteration of the artery by cold will persist. The importance of this factor is demonstrated by patients who show a good result in one hand and a poor result in the other after what were intended to be identical operations on the two sides. Anatomical variations in the origin and distribution of sympathetic rami are well known, and it is therefore essential to plan our operations so that there is the least possible risk of missing a few of them. It must not be forgotten that nerve impulses are mediated by chemical substances liberated at nerve endings, and widespread contraction of muscle may therefore result from the sparing of single nerve filaments.

For this reason we now favour the posterior approach to the upper thoracic sympathetic trunk as modified by White and Smithwick (1942). Though the anterior approach as modified by Telford (1935) can achieve the same object in skilled hands, the less experienced are likely to find the posterior approach a simpler operation, and resection of the medial ends of the second and third intercostal nerves is a good safeguard against sparing any anatomically abnormal filaments.

It will be noted that these operations are designed to make a preganglionic section of the vasomotor supply to the arm. Removal of the second, third, and fourth lumbar ganglia, the usual operation for sympathetic denervation of the lower extremity, is a purely preganglionic section for the foot. It is well known that the sensitization of sympathetic nerve endings to adrenaline is less after preganglionic than after postganglionic section; and as this sensitization plays a part in restoring a degree of vasoconstriction and so producing "recurrences" after operation for Raynaud's disease, the importance of planning a preganglionic operation is manifest. The uniformly better results obtained by operation for Raynaud's disease of the feet are often accounted for entirely on the ground that the lumbar operation is preganglionic, whereas in the thoracic operation some postganglionic elements also may be damaged. But it must be remembered that the disease

* From the Surgical Professorial Unit, St. Bartholomew's Hospital. Lecture given at the Royal College of Surgeons of England, Nov. 29, 1945.

is never as severe in the foot as in the hand. Ulceration and sclerodactyly of the toes are almost unknown.

It is often said that sympathectomy is effective only for a few months or a year, suggesting either that nerve regeneration is the rule or that the peripheral remnants of the sympathetic can function independently. But the sympathetic denervation following a well-planned and correctly executed operation is permanent, as shown by sweating tests in addition to vasomotor reactions. In progressive structural disease symptoms may persist and increase in severity; certain organs may be capable of acting without nervous control; but these manifestations must not be misinterpreted as evidence of failure of sympathectomy. They show that there may have been an error of judgment in selecting patients for operation, and so far as Raynaud's disease is concerned the predominant consideration must be the severity of the disease. Milder forms react favourably to sympathectomy: the operation is often futile in the presence of complications, especially scleroderma.

Obliterative Arteritis

Structural disease in the arteries of the leg is of many varieties with many different causes, ranging from injury to thrombo-angitis and arteriosclerosis—presenile, senile, and diabetic. But whatever may be the aetiology, it is the level of the block in the arterial tree which determines the clinical picture and the value of sympathectomy in its treatment. This important fact was demonstrated arteriographically by Boyd in 1938, yet it is still commonly taught that in any form of obliterative arteritis the disease runs a progressive course characterized by intermittent claudication in the early stages, followed later by rest pain.

Actually three clinical groups may be recognized. In one a main vessel such as the femoral or more commonly the popliteal artery is thrombosed and the presenting symptom is intermittent claudication in the calf muscles. Though the foot may be appreciably colder than the other—for the disease is often unilateral—the nutrition of the skin of the foot remains good and gangrene does not occur, since the proximal vessels alone are involved and an adequate collateral circulation develops to keep the distal vessels supplied. It must be noted that if the posterior tibial artery is blocked in this way intermittent claudication in the muscles of the sole of the foot is the result, but may be mistaken for "foot strain."

When the popliteal artery is thrombosed the sural arteries supplying the gastrocnemii are likely to be permanently blocked, causing irreparable damage because of the poor anastomosis within the muscle itself. It is therefore not surprising that sympathectomy is of little or no value for claudication arising in this way. If, however, the block is in the external iliac or femoral arteries the outlook is much better, since the post-operative improvement in the collateral circulation at the level of the block provides a considerable increase in the blood flow to the calf and we have had enough experience to convince us of the great value of sympathectomy in these more proximal blocks.

The diagnosis can be made by anyone who has learnt to feel the pulse in the popliteal artery. This is too often regarded as a difficult examination and is therefore neglected. All the pulses in the leg—femoral, popliteal, posterior tibial, and dorsalis pedis—must be felt for as a routine examination. More accurate information is obtained by oscillometry, but this is rarely required for diagnosis: it is of much value in assessing the severity of the disease, and is therefore useful for prognosis.

The intensity of postural colour changes in the foot, and the rate at which superficial veins refill after they have been emptied by elevating the limb, are helpful in indicating the degree of arterial obstruction.

These simple clinical methods usually provide all the information required to make a decision for or against sympathectomy, but brief reference must be made to the more complicated tests with local or spinal analgesia, and to arteriography. Spinal analgesia produces vasomotor paralysis, but the local blocking of sympathetic trunks with procaine has the advantage that muscle power is preserved, and so it is possible to test the effect upon claudication by getting the patient to carry out repeated movement against resistance under controlled conditions before and after the injection.

The duration of the sympathetic paralysis in these tests is brief, and whereas a good response is an argument in favour of operation, a poor response should not be sufficient in itself to deny a patient any chance of relief by sympathectomy. The improvement in collateral circulation which accounts for any post-operative improvement in the limb is a gradual process, and this explains the well-known fact that the results of sympathectomy for obliterative arteritis are usually better than tests by temporary nerve-blocking might lead us to expect.

It is often said that it is only when spasm is an important factor in the disease that sympathectomy is worth while. But an improvement in the blood flow after spinal analgesia is not evidence that spasm has been relaxed, for it is the reaction produced in any normal individual. It really means that the arteries are capable of relaxing fully when vasoconstrictor impulses no longer reach them, and a poor response indicates that the structural changes of degeneration or inflammation interfere with this normal reaction. No doubt spasm does play a part in obliterative arteritis, but its importance has been greatly exaggerated.

Another disturbing dictum is that sympathectomy is contra-indicated for claudication because, if the operation is successful and the circulation in the skin is improved, there must necessarily be a corresponding impairment of the deep circulation to the muscles. There is experimental evidence that sympathetic impulses are vasodilator to the arteries of skeletal muscle, and this provides a strong theoretical argument against sympathectomy for claudication. We have enough practical experience, however, to show that the operation is often beneficial, and our disappointments are to be explained by the obliteration of certain important muscular branches. Arteriography is the only pre-operative examination which can give us information on this point, but it must not be assumed that this test is often necessary, as the decision about operation can usually be made without its aid.

In the second clinical group the distal arteries, of the size of the plantar arch and its digital branches, are principally affected, and the characteristic features are pain in the foot at rest, often worst in bed at night, and nutritional changes in the skin—discoloration, ulceration, and gangrene. When dependent the toes or the whole foot are of a reddish-blue colour, and they blanch when elevated above heart level. Permanent discoloration of the affected parts heralds the onset of gangrene. The pulse in the main vessels, at the knee and even at the ankle may be present, and under such circumstances there is a abrupt drop in the surface temperature at the level of the arterial obstruction.

Sympathectomy can achieve a great deal in this distal group: the intense pain is often abolished, and if it persists it is because gangrene has already been established. The improvement in the circulation in the foot after two or three weeks may be sufficient to permit the successful local amputation of toes and if the stump fails to heal and pain recurs we know that major amputation is necessary, though it may be done below the knee.

In the third group there is widespread narrowing of the lumen throughout the arterial tree. Rest pain follows closely upon intermittent claudication, and gangrene of the toes occurs with loss of the pulse in the main vessels at the knee or at the groin. Under such circumstances sympathectomy is useless, and amputation above the knee becomes inevitable.

Arterial Injuries: Early Treatment

For small lacerations simple suture may be effective, and it is available fibrin foam is valuable in strengthening the repair. For more extensive wounds, in which suture would narrow the lumen unduly, complete division with axial anastomosis, or the re-establishment of the stream using a cannula or vein graft is preferable to complete division and ligation of each end, though the last may be the only possibility under conditions of stress. It is unfortunate that so often the conditions under which the wound has to be treated preclude any long and delicate procedure requiring special apparatus. The attempt to restore the lumen, even if it succeeds only for a short period, may be of the greatest value if it gives time for the establishment of a collateral circulation before the vessel finally becomes blocked.

It must always be remembered that, if the artery has to be ligated, double ligation by itself is not enough—in fact, it is dangerous because the longitudinal tension in the artery increases the risk of secondary haemorrhage. The damaged segment must be excised, and not for this reason alone, since it may set up spasm in the peripheral arteries. Excision may be regarded as the most radical form of periarterial neurectomy, which explains the post-operative improvement in the colour and temperature of the limb.

These remarks also apply to contusion of an artery such as may follow a "near miss." It may be a difficult matter to determine whether an artery is constricted because it is bruised or merely because it is in spasm, from which, of course, it may recover within 24 hours. If there is much discoloration it is more than likely that intimal damage will cause thrombosis, and it will usually be wise to excise the damaged portion. If in such a case it is decided to postpone excision because blood is still flowing through the constricted part of the artery the surgeon should be prepared to reopen the wound within 12 or 24 hours if there are no signs of improvement in the peripheral circulation. By this time the appearance of the vessel should indicate clearly what ought to be done.

When an artery has to be tied soon after an injury we would follow Makins's teaching and tie the companion vein. Reference will be made later to the inadvisability of tying the vein in the later stages.

Should sympathectomy be performed—or at least injection of the sympathetic supply with local analgesic solution or alcohol—to encourage collateral circulation after the sudden block of a large artery? There are animal experiments to show the value of sympathectomy under such circumstances, gangrene being greatly limited in extent or avoided altogether. There is also much clinical evidence of the value of sympathectomy as a preliminary to ligation of a main vessel, such as the popliteal artery, which is known to carry a serious risk of gangrene. But the assessment of sympathectomy after wounding of a main artery is a different matter, and we must await the full report of the Army's forward surgical teams before drawing any conclusions. My own experience of a few patients upon whom sympathectomy or injection had been performed shortly after wounding was unfavourable, but there may have been many successfully treated at the front who were therefore never sent to a vascular centre at the base.

There are, however, many other measures which should be taken to give the best chance of survival to a limb threatened with gangrene. The most simple, and perhaps the most important, is attention to the position of the limb. If it is too much elevated it will become pale and cold, because of the free drainage of blood out of a limb which has a very limited supply. If it is allowed to hang down it will become cold and blue from venous congestion. In both of these positions pain may be severe, but an optimum position may be found which is most comfortable, and in which the limb is warmest and of the best colour—it is usually with the limb extended at or just above heart level.

Reflex vasodilatation of collateral vessels may be brought about by heating the trunk and the healthy extremities, but the affected limb must be kept cool—either exposed to room temperature, or even cooled by a fan or ice packs. Warming a limb increases the local tissue metabolism and therefore the demand for blood, cooling has the opposite effect, and thus tends to reduce the need for oxygen to approximate to the amount which can be supplied by the impaired circulation.

Rapid transfusion of a pint (473 ccm) of blood may have the effect of forcing open collateral vessels, and is naturally especially valuable after severe blood loss.

Traumatic Aneurysm and Arteriovenous Fistula

In managing these later results of arterial injury it is most important to bear in mind that the safety of the limb depends upon delaying operation to provide time for an adequate collateral circulation to develop. As a rule there is no difficulty about waiting for three months or more when there is a fistula, since the force of the arterial pulse can diffuse easily into the open vein without much, if any, increase in the size of a false aneurysm sac. But with an injury which is purely arterial it

happens not infrequently that a steady increase in the size of the false sac, and in the severity of pain, necessitates intervention at an earlier date. In our own limited experience I have been forced to operate upon one brachial and three axillary false aneurysms within a month of wounding.

This experience has brought it home to me that the usual description of the production of a traumatic false aneurysm does not cover all of them. It is said that the haematoma which forms immediately upon the arterial wound becomes hollowed out like a cup, the original clot thus forming the wall of the sac. When this happens the wall must be fairly substantial and when organized should provide a strong fibrous barrier against the arterial pressure. Fresh layers of clot would form within the sac, so that spontaneous cure of a small aneurysm may follow. I believe that I have seen this occur in two of our soldiers.

But the aneurysms which demanded early operation gave clinical signs of having thin walls which yielded alarmingly to the pulse beat, and when they were opened there was a central mass of blood-clot surrounded by fluid blood within the very thin and imperfect sac wall formed by the surrounding muscle and connective tissue. I wonder how frequently this may be the state of affairs in traumatic false aneurysms. I suspect more frequently than current teaching would lead us to expect.

The definitive treatment of a traumatic aneurysm is extirpation of the sac whenever this is possible, but for the brachial aneurysm and two of the axillary aneurysms which required earlier operation I performed proximal ligation as close as possible to the aneurysm as a preliminary measure ("immediate proximal ligation"). This was done to reduce the size of the swelling, which threatened to rupture and also compressed neighbouring collateral vessels, to give further time for the development of a collateral circulation, and to facilitate the direct approach to the aneurysm itself three or four weeks later. For one of them—an aneurysm of the third part of the axillary artery—I combined the preliminary ligation with upper thoracic sympathectomy. The nutrition of the limb did not suffer, nor was the second stage of the operation rendered more difficult by the first stage of this double procedure.

Before deciding upon proximal ligation however, it must be clearly established that the lesion is purely arterial for this operation carried out on an arteriovenous fistula is fraught with grave danger and may be disastrous because the ligature interferes seriously with the developing collateral circulation at the level of the fistula, without impeding in any way the too easy return flow of blood into the veins. The danger was well illustrated by a patient transferred to us after ligation of the external iliac artery for a large varicose aneurysm of the femoral artery which also involved the origin of the profunda. As soon as he had recovered from the anaesthetic he was found to have an external popliteal nerve palsy and a cold painful foot which showed all the manifestations of severe ischaemia, though gangrene fortunately never became fully developed.

Diagnosis of Arteriovenous Fistula

An arteriovenous fistula can be recognized by the character of the bruit which is heard over it and is conducted for great distances proximal and distal to it. It is a continuous whirling clattering sound with a systolic crescendo, and well deserves its common designation of "machinery murmur." This should be sufficient in itself to distinguish a fistula from an arterial aneurysm with its systolic bruit.

There are many other associated signs, of which tachycardia and an increase in pulse pressure, owing to a drop in the diastolic blood pressure, are usually the first to be recognizable. The increase in pulse rate may not be noticed until the remarkable slowing of the pulse which follows obliteration of the fistula by digital compression has been observed. Only one of our 34 arteriovenous fistulae was associated with a cardiac murmur, and overfilling of superficial veins was rarely seen. These would appear to be later developments. All of our patients showed some degree of enlargement of the heart though very few were reported by the radiologist to be beyond the normal limits, the heart decreased in size in every one after closure of the fistula, yet it is clear that the diagnosis cannot be made by this method. The blood volume also was less after

closure of the fistula in every patient thus examined; but although it is possible in the end to say that the blood volume was shown to be increased on the average by about 15%, as the "normal" blood volume of a given individual is not known the pre-operative figure can scarcely be expected to provide evidence of a fistula.

It is much more difficult to decide where the fistula is and what vessels are involved. The loudness of the bruit is deceptive, and the determination of the point where pressure will abolish it may not be an accurate guide, because compression of the main vessel proximal to the fistula can give the same result. Arteriography, which is a great help when a main vessel is obstructed, usually fails to give a clear picture of a fistula, especially if it is large enough to allow the opaque material to diffuse rapidly into the vein. The track of the missile as shown by a through-and-through wound or a retained foreign body is often the best guide. But the decision usually has to be made by guesswork, and over and over again one has felt that the whole undertaking would have been so much simpler had one started with the information which has to be gathered in the course of the operation.

Treatment of Arteriovenous Fistula

We learnt that for safety it is necessary first to pass controlling tapes round the artery and vein involved as near as possible above and below the fistula without opening into it. In a bullet wound this may be comparatively simple, but as most of the wounds were caused by fragments of mortar shell or bomb, and as there had clearly been widespread haemorrhage with subsequent scarring inside and outside the vessel sheath, it was often a tedious dissection to clear the required length of the artery without damaging branches which were needed as collaterals. For the same reason it is often difficult to find healthy enough vessel wall to hold sutures, especially with varicose aneurysms, and I often felt humiliated by my lack of enterprise, for we were commonly reduced to quadruple ligation instead of carrying out the various forms of arterial reconstruction which we had hoped to attempt. On the other hand, it must be admitted that the results obtained by this "old-fashioned" method were not unsatisfactory.

We carried out lumbar ganglionectomy two to three weeks before all our operations for arteriovenous fistula in the lower extremity, with the single exception of a fistula between the peroneal artery and vein. We did this partly because our series was intended to link up with that of Lieut.-Col. A. M. Boyd, and I understood that this was also his practice; partly because, even in spite of waiting for a collateral circulation to form, damage might be done to it in the course of the dissection of the lesion, and the best possible collateral circulation therefore seemed to be desirable; and partly also because I knew that at other centres these fistulae were being treated without sympathectomy and I hoped our series might form part of an interesting controlled experiment. It may yet appear that we were unnecessarily over-cautious, but we never saw anything approaching gangrene of a toe. It would be wrong to draw conclusions from our small numbers—1 common femoral, 3 superficial femoral, 5 profunda femoris, and 7 popliteal lesions—but they all recovered with good function. The most critical was in the man who had already had his external iliac tied in continuity for a common femoral arteriovenous fistula: after a preliminary lumbar ganglionectomy I was forced to do a "triple arterial" ligation of his common, superficial, and deep femoral arteries, yet six months later he was able to walk four miles without pain, his residual disability being due to the ischaemic palsy of the external popliteal nerve, which was steadily recovering.

While quadruple ligation was in our experience the usual treatment for arteriovenous aneurysm, it may be possible to vary the procedure for aneurysmal varix. The scarring is less as a rule—no doubt the direct opening of the artery into the vein serves to limit the amount of blood extravasated into the surrounding tissues—and the dissection of the lesion is more straightforward. In two popliteal fistulae after the vein had been tied above and below the fistula it was possible to narrow down the communication till it could be safely ligated as though it were a branch of the artery, and thus the artery itself was spared.

Syndrome of Venous Obstruction

We were rather surprised, however, to note that these patients whose popliteal artery was preserved at the cost of the vein were less comfortable than those who had had both vessels blocked by quadruple ligation. They complained of aching pain and a bursting feeling in the lower leg, ankle, and foot produced by lowering the leg, which was more severe in the standing than in the sitting position, though sitting in one position for an hour or so may be almost intolerable. The pain may be relieved by walking for a short distance, but the quickest and most effective method of easing the pain is by lying down with the legs raised above "heart level." Swelling round the ankle may accompany the pain.

We came to recognize these symptoms of venous obstruction in many patients after injury or operation, but we also noticed that they are more marked when the arterial supply is unimpaired. Being persuaded that when ligating an artery immediately after an injury simultaneous ligation of its companion vein is advisable or is at least harmless, it took us a long time to realize that the different conditions under which ligation is undertaken at a later stage may call for different treatment. We had thought, with others, that in the treatment of an arteriovenous fistula, while immediate proximal and distal ligation of the artery would be sufficient to stop the vicious circulation the additional ligation of the vein would be better (Maybury 1945).

But the recognition of these symptoms as those of venous obstruction made us think again, and we were able to put the matter to the test in two fistulae—one between the profundus femoris artery and the common femoral vein, and the other between the superficial femoral artery and vein. For both of these we ligated the artery as close as possible above and below the fistula but left the vein intact. Neither of the patients complained of any of the symptoms of venous obstruction, and both had an adequate peripheral-arterial supply. It is therefore our impression that the collateral circulation resulting from an arteriovenous fistula safeguards the arterial flow to the limb after ligation of the artery, and that it is a distinct advantage to preserve the vein whenever this is possible.

OBSERVATIONS ON CASES OF STARVATION AT BELSEN*

BY

P. L. MOLLISON, M.D., M.R.C.P.
Capt., R.A.M.C.

Belsen was a detention and not an extermination camp—that is to say, not a camp where organized extermination was carried out. Originally devised for perhaps a few thousand people, it became progressively more overcrowded in the early part of 1945 as the Allied armies closed in from west and east and forced the Germans to evacuate other concentration camps. At its peak it is said to have contained over 66,000 persons. The majority of these were Jews of Polish or Hungarian origin, but almost all countries and religions were represented. Many of the patients had spent only short periods in Belsen, having previously been interned in other concentration camps, such as the notorious one at Auschwitz. However the following notes, based on information given by a Hungarian woman doctor who was in Belsen for four months, convey some idea of the diet on which they had existed before the liberation of the camp.

In Jan., 1945, there was already very little food, but the quality was not so bad. Each person got one-sixth of a loaf a day (the loaf was black and weighed about 1.4 kg.), and sometimes potatoes and pieces of meat. For instance, there was occasionally a thin slice of sausage for supper and a little meat in the soup. On Sundays tinned meat was distributed; 15 persons shared one tin. By February everybody was getting

* An abstract of a report to D.M.S. 21 Army Group.

thin and the epidemic of typhus started. From then onwards the food steadily deteriorated. For a time they received soup on three nights a week and a little margarine or jam on the other four nights (only one twelfth of a loaf each during March and no bread at all in April). When there was no bread they were given mangel wurzels so that sometimes supper would consist of mangel and margarine. For the last fortnight before the camp was relieved (i.e. for the first fortnight in April) mangel-wurzels were the only food. These were distributed in a form of soup sometimes made from flour and salt, sometimes from neither. During this final period each internee was getting about a half-litre of this soup a day and nothing else. It is evident that throughout the last weeks of the camp's existence a gruesome form of the law of the survival of the fittest was in operation. The distribution of food was arbitrary, and those that still had some strength left obtained more than their share. An idea of the general conditions prevailing during the few weeks before the arrival of the British may be gained from the official statement that 10 000 unburied corpses lay among the living when the camp was first reached by them.

The original concentration camp, where the thousands of internees lay in crowded huts, was gradually evacuated between late April and the end of May. During this time innumerable seriously ill patients had of necessity to await their turn and to remain in the huts for a further period of days or even weeks under most unfavourable conditions. The patients were first seen after they had been brought from the concentration camp passed through the 'human laundry' for disinfection, and taken to beds in the barrack rooms that formed the 'hospital' accommodation. The following description of the clinical state is based on the appearance of patients in the middle of May—about four weeks after the first arrival of the British in the area.

A Typical Clinical Picture

The patient lay flat in bed without acute distress, yet with a miserable expression. He showed no interest in anything except his own needs, and appeared completely indifferent to the deaths that occurred so frequently. Moreover, death was a very public affair, since there were no screens and beds were crowded together. He talked with a whining voice and complained continually, usually of his severe diarrhoea. 'Schweizerei' was the commonest word. Second only to this complaint was unfavourable comment on the diet, the soup being blamed for the diarrhoea. Black bread was next in unpopularity. Patients who were a little less ill asked continually for white bread and complained that they were being starved. The truth was that there was enough food in terms of calories, but much of it was unpalatable. Although starving they were extremely particular about their diet and very difficult to please. Most of them did not fancy sweet things, and almost all wanted solid food rather than soup. When they wanted a drink, lemonade or something sour was most often asked for. They were all sure that soup and cold food made the diarrhoea worse. Although milk was available as an alternative to the full diet, many of the patients didn't want it, and, if given it, complained that they were not getting enough to support life. Because of their poor appetite, many of them left their food untouched, and as there were insufficient nurses to feed them their state rapidly became worse. The orderly simply put the food beside the bed and left it. Later the untouched food would be collected if the patient had not secreted it in his bedding for future use. Fear of being without food was so great that even dying patients would put bread and butter and meat under their pillows.

All the seriously ill were incontinent of faeces, and their beds were continually soiled as there were not enough orderlies to change them and, in any case, many of them had no sheets but simply lay on covered pallets. Almost every patient when first seen had diarrhoea—varying from two to three loose stools a day to an almost continuous production of watery stools. In the latter cases a movement of the bowels invariably followed immediately after taking anything by mouth, so that the patient was afraid to eat or drink. The stools did not as a rule contain blood or pus. They were often light brown in colour, smelt offensive, and consisted of fluid and lumps of undigested food.

On examination the patient had an appallingly thin face. The eyes were sunken and the cheek bones jutted out. These

extreme changes made all the patients look alike, so that it became difficult to distinguish one from another. This difficulty was accentuated by the fact that all patients had had the bulk of their hair shaved off. The skin of their arms, legs, and anterior abdominal wall was often rough, dry, and scaly. There were large bed-sores on the buttocks and the lower part of the back. The ribs stuck out, and it was difficult to use a diaphragm type of stethoscope because it simply bridged across two ribs and made no contact with the skin dipping down in between. The anterior abdominal wall was concave, falling away from the ribs above and from the anterior superior iliac spine below. The greatest muscle wasting was around the pelvis. The iscal tuberosities stood out prominently and the posterior surface of the ilium was almost devoid of muscle. There was a depression below the anterior superior iliac spine, and the hip flexed to the thigh in a fold. The legs were fuller owing to oedema, but this was often confined to the ankles and feet, so that a common appearance was of a leg as thin as a stick with a fat swollen foot on the end of it.

The face and hands were pale. The conjunctivae were pale but otherwise normal. The sclerae were clear. The tongue was often red and smooth around the edges but extensive changes were not seen. Koilonychia was not seen in a single case. Many patients had sore dirty mouths with gingivitis when they first arrived in the hospital area, but this condition cleared up in a few days without special treatment. Angular stomatitis was present in a small proportion of cases. The pulse was usually rapid (average approximately 100 beats a minute) and the blood pressure low (the average in 12 emaciated patients being 91/60). No abnormalities were discovered in the heart apart from a reduced intensity of the sounds.

The average weight of 18 males who were strong enough to stand upright on scales was 44 kg (38.7–59.7). 11 females averaged 35.3 kg (25–45.5), i.e. males just under 7 st., females about 5 st. In 11 of these 29 the previous weight was known and the loss was calculated as a percentage of the figure in health (the average loss was 38.8% (29–57%)—see Table I. The

TABLE I—Relation between Loss of Body Weight and (1) Haematocrit and (2) Serum Protein Concentration in 11 Subjects

Case	Date	Body Weight (Kg)			Loss of Weight (%)	H _{ct} (%)	Serum Protein (g/l)
		Now	Originally	Loss			
M 42	June 8	35.0	80.0	45.0	56	14	4.9
F 116	July 5	25.0	70.0	45.0	64	6	4.8
F 1	June 19	34.0	63.0	29.0	45	12	4.3
M 37	June 7	39.0	67.0	28.0	42	2.0	4.6
M 114	July 3	35.1	56.0	20.9	37	31.0	4.6
F 119	June 19	52.0	62.0	10.0	16	3	3.7
M 35	June 7	32.0	40.0	8.0	20	2.0	6.9
F 111	July 3	31.0	47.0	16.0	34	20.2	4.0
F 124	July 18	33.2	45.0	11.8	26	3.0	4.0
F 101	June 8	33.0	47.0	14.0	30	2.0	4.0
F 4	May 25	40.0	33.0	7.0	18	31.9	6.0

* B—All above patients except M 37 and *1-2 were non-tuberculous. No patient with more than a trace of oedema was included.

patients in this latter group were weighed at a comparatively late date (6 in June, 5 in July and 1 in May) and, although all were very thin and at least one case of extreme emaciation included (F 116) the figures do not on the whole represent the most severe cases. The thinnest patients died earlier and had been too ill to be weighed. As shown in the table, there was no correlation between percentage loss of body weight on the one hand and either haematocrit or serum protein concentration on the other.

Pulmonary Tuberculosis

Those who were free from pulmonary tuberculosis and had not reached the stage of extreme emaciation usually made rapid progress. They were soon able to eat almost any kind of food and their diarrhoea diminished although they continued to be very prone to loose stools and hurried evacuation of the bowels after meals. It was quickly realized that any patient whose progress was unsatisfactory was likely to have tuberculosis. During the last week in May it became possible to screen the chests of a few of those whose blood had been examined. Later some patients were transported to a static x-ray plant and chest films were taken. From this evidence and from post mortem findings it was possible to say with some precision that certain

patients had tuberculosis and that certain patients were free from it. There were left some who were not x-rayed and who had no clinical signs of the disease.

Of 36 males 13 were free from tuberculosis, 7 were probably free, and 16 were affected. Of 28 females 9 were free, 8 were probably free, and 11 were affected. Thus, in all, the incidence of definite pulmonary tuberculosis in this series was at least 27 out of 64 cases, or approximately 40%, and it may have been higher. This incidence is of course in no way representative of all the victims of Belsen Concentration Camp, since many were never admitted to the hospital area. Furthermore, patients whose blood was examined were selected mainly on the grounds of being more sick than the average. On the other hand, some were selected for reasons irrelevant to their state of health—e.g., because they were doctors. All that this figure represents, therefore, is the approximate incidence of pulmonary tuberculosis among those who appeared rather more ill than the average. The incidence in those who died was probably considerably higher. Thus among 18 cases in which the cause of death was established an extensive tuberculous infection was present in 12.

TABLE II.—Summary of Blood Findings

Group	No. in Group	R B C per c mm	Hb (%)	Hb (g. %)	Hmt. (%)	M.C.H.C. (%)	C I	M C V. (μ^3)	Serum Protein (g. %)
Starvation cases (males)									
Non-tuberculous									
Good evidence	9	3,403,000	62.2	9.7	30.9	31.4	0.91	91.4	5.6
Insufficient evidence	7	3,610,000	66.9	10.4	33.6	30.9	0.93	93.4	4.7
Tuberculous									
Pleural effusions only	5	3,450,000	61.4	9.6	29.8	32.2	0.89	86.6	4.8
Active pulmonary Tb	9	3,380,000	60.1	9.4	29.8	31.8	0.90	88.6	5.4
Average	30	3,450,000	62.5	9.8	31.0	31.5	0.91	90.2	5.2
Starvation cases (females)									
Non-tuberculous									
Good evidence	8	3,310,000	60.2	9.4	29.3	31.7	0.91	89.0	4.3
Insufficient evidence	6	3,060,000	52.7	8.2	27.5	29.9	0.86	90.0	5.2
Tuberculous									
Active pulmonary Tb	9	3,130,000	57.9	9.0	29.2	30.9	0.92	94.0	5.2
Average	23	3,180,000	57.3	8.9	28.8	31.0	0.90	91.0	4.9
Starvation cases (children)	7	3,520,000	61.2	9.6	29.9	31.9	0.87	85.5	6.0
Controls (healthy British males)	12	5,255,000	98.7	15.4	47.2	32.7	0.94	90.0	6.7

It was noted that some of the very frail patients remained afebrile despite tuberculosis—e.g., M 37, an extremely emaciated man of 50 years, whose temperature, taken twice daily for the last three weeks of his life, never exceeded 37°C., but who at necropsy was proved to have had active recent tuberculosis with cavitation. It was also frequently observed that patients coughed far less than would be expected from the extent of the pulmonary lesion, and several patients with active infection did not cough at all.

Typhus

The typhus epidemic in Belsen apparently started in February, and cases continued to occur until about the end of May. It was very difficult to discover in any individual cases whether or not a patient had had typhus, because so many had been desperately ill and weak for some time before the liberation and could not give any exact description of the kind of illness they had had. Weil-Felix tests were carried out in 48 cases: 21 were positive in a titre of 150 or more; 27 were negative or gave titres lower than 150. Of 26 of these tests made in May, 12 were positive; and of 22 made in June or early July, 9 were positive. Of 19 patients who said they had not had typhus 10 had negative and 9 had positive Weil-Felix reactions. Of 9 patients who said they had had typhus 5 had positive and 4 had negative Weil-Felix reactions. (I am indebted to Majors Griffin, Morris, and Prior for performing these tests.)

The general conclusion reached must be that the majority of patients in Belsen had recently had typhus.

Blood Examinations

Notes on Methods.—(1) All blood examinations were made on venous samples. (2) Haemoglobin was estimated as alkaline haematin; the majority of the measurements were made in a photo-electric colorimeter. Solutions were prepared from

crystalline haemin (81 mg. to a litre of N/10 NaOH) to make standards corresponding to 15.6 g. haemoglobin % (King *et al.*, 1937). The average density of these solutions, when checked against a standard grey screen, was found to be within 0.5% of that given by King *et al.* (3) Serum protein concentrations were deduced from specific gravities, using the copper sulphate method of Phillips *et al.* (1945). (4) Plasma volume was estimated by the dye dilution method, using Evans blue. A single blood sample was obtained 10 to 15 minutes after the injection of the dye. The dyed plasma was sometimes measured directly; in other instances the plasma was first treated to remove other pigments (methods of Crooke and Morris, 1942, or Morris, 1944).

Findings

(The majority of the estimations were made between May 14 and June 14—that is to say, within 4 to 8 weeks of the first arrival of the British Army in Belsen.)

Widespread Anaemia (see Table II).—75 starvation cases (36 males, 32 females, 7 children) were tested. Many of them were chosen because they were pale or oedematous or rather more wasted

than the average, but some included were less severe cases of starvation who later showed rapid improvement. With the exception of a few severely dehydrated patients (excluded from this series), all persons examined were found to be anaemic. Tuberculosis was evidently not the main cause of this anaemia, since there was very little difference between the Hb levels of the non-tuberculous and the tuberculous cases.

Haemoglobin Values.—The average haemoglobin in 30 males was 62.5%, in 23 females 57.2%, and in 7 children 61.2%. Almost all these observations were made between the middle of May and the middle of June (males, 19 in May and 11 in June—latest June 19 females, 17 in May, 2 in June, 4 in early July). One feature of the observations was the comparatively small scatter of the haemoglobin values. The following indices were calculated:

Group	No	Mean Hb %	S D	Coeff of Variation
Belsen males	30	62.5	7.3	11.6
Belsen females	23	57.3	9.3	16.6
Controls (males)	12	98.7	4.6	4.6

Characteristics of the Anaemia: Normochromic, Normocytic.—A striking feature was the absence of any evidence of iron deficiency. Thus the M.C.H.C. in a group of 30 males was 31.8% (lowest 29.4%), and in a group of 23 females 31.0% (lowest 26.7%). These averages do not differ materially from the average M.C.H.C. found in a group of 12 healthy British Army personnel—viz., 32.7%. Mean corpuscular volumes showed slightly larger variations than those of the control group; but average figures were normal—namely, 90.2 μ^3 in a group of 30 males and 91.0 μ^3 in a group of 23 females, compared with 90.0 μ^3 in the control group. The examination of stained films confirmed the absence of any significant change in average cell size, though some cases showed a rather greater degree of anisocytosis than normal. The features of normocytosis and normochromia of the erythrocytes suggest a simple diminution of production rather than any abnormality of maturation. This conclusion receives support from examination of the few marrow films that were made, on which Dr. J. F. Louit reported as follows:

"Erythropoiesis is normoblastic, and so far as one can tell there is no maturation defect." The reduced metabolic rate which is known to prevail in starvation was probably one of the chief causative factors in this diminution of production, and doubtless in many cases infection of one kind or another had also contributed to a depression of bone marrow. The lack of correlation between haemoglobin and serum protein levels (see below) suggests that protein deficiency was not the main cause of the anaemia.

Reticulocytosis Present.—Reticulocyte counts were made on 20 patients who had been on a normal diet for at least five weeks but had received no iron or liver or other special treatment. The average was 1.6%. In 10 non-tuberculous subjects the average was 1.9% (range 0.6-3.6%); in 10 tuberculous subjects the average was 1.3% (range 0.5-2.4%).

Hypobilirubinemia.—Although serum bilirubin estimations were not made, it was repeatedly observed that the sera were pale and often almost colourless.

Leucocyte Counts, including Differential Counts.—Only a few leucocyte counts were made; these were within normal limits. The height of the leucocyte column in the centrifuged haematocrit was measured in all cases. The average was 0.8 in 40 males and 0.9 in 26 females. In 12 normal soldiers the average was 0.8. In 7 of the 66 cases the column was less than 0.4 of a division. However, 5 of these 7 died within four days of taking the samples. There is therefore some evidence that leucopenia was not a striking or consistent feature of these cases of starvation.

Serum Proteins.—Total serum proteins were estimated in 43 cases. In 18 males the average figure was 5.2 g.%. In 19 females the average was 5.0 g.%. In the oedematous cases the levels were on the average lower than in the non-oedematous, although in many individual cases there was a lack of correlation between total serum protein concentration and degree of oedema (see Table III).

TABLE III.—Relation of Serum Protein Levels to Oedema

Group	No. of Cases	Average Serum Protein Conc. (g. %)	Range of Serum Protein Conc. (g. %)
Severe oedema	4	4.0	3.6-4.4
Moderate oedema	10	4.7	3.5-6.5
Slight oedema	13	5.1	4.5-5.6
No oedema	23	5.8	4.5-7.5

N.B.—Slight oedema was defined as oedema involving only the feet and ankles. Moderate oedema was defined as oedema involving the legs as well as the feet; in some of these cases the oedema extended to the lower part of the back; in others it did not extend above the knee. The term "severe oedema" was reserved for those cases which had generalized oedema involving the face. In all these cases the urine was either completely free from protein or contained at most a trace.

Lack of Correlation between Haemoglobin Values and Serum Protein Concentrations.—No correlation was observed between haemoglobin levels and serum protein concentrations. It is noteworthy that the average haemoglobin level was proportionately more depressed than the average serum protein concentration—viz., average haemoglobin level about 60% of normal, average serum protein concentration about 75% of normal.

Blood Volumes (see Table IV)—Plasma volumes were estimated in 6 males and 10 females, and blood volumes were deduced there-

TABLE IV.—Blood Volumes

Case	Weight (kg.)	Oedema	P.V. (litres)	Hmt (%)	B.V. (litres)	S.Pr. (g. %)	B.V. in c.cm., kg.

AV.				29.0 (10 cases)	3.7	—	—

* In these cases the dyed serum samples were not measured directly, as they were in the others, but were first treated to remove other pigments, etc.
(a) Blood volume estimated 12 hours after a serum transfusion, which had lowered the haematocrit from 29% (before the transfusion) to 26% (at the time the blood volume was estimated).
(b) Blood volume estimated after an infusion of 500 c.cm. inulin-saline solution. The haematocrit before the infusion started was 32% and at the time of estimation of the blood volume 30%.

from, using haematocrit readings. The average figure for total blood volume was 4.30 litres in the males and 3.17 litres in the females. It is felt that the figures for females are the more reliable, as these were, with one exception, estimated by the same technique—namely, the direct measurement of the dye in serum.

In 12 of the 15 cases in which body weight was known, the relation of blood volume to body weight varied from 85 to 125 c.cm./kg., averaging 101 c.cm./kg. in 6 males and 95 c.cm./kg. in 6 females. These figures are high compared with the normals of Gibson and Evans (1937)—viz., 77.7 c.cm./kg. for males and 66.1 c.cm./kg. for females. Thus it appears that blood volume in seriously undernourished subjects is not reduced in proportion to body weight. Three other females were found to have far lower ratios of blood volume to body weight—viz., 61, 63, and 69 c.cm./kg. respectively. These three patients all had considerable oedema. However, at least one other patient with a corresponding degree of oedema did not show this relation. All that can be said, therefore, is that, in the presence of oedema, blood volume either bore the usual relation to body weight or was relatively lower. In Case F 110 the blood volume was estimated a second time, after a considerable amount of oedema fluid had been lost; a slightly higher figure was obtained on the second occasion, although the patient had lost 12 kg. in weight. This observation is in agreement with the hypothesis that blood volume in severely oedematous cases is related to the tissue mass and is not increased in proportion to the extra weight of oedema fluid.

Serum Urea.—Serum urea was estimated in over 40 patients, and in some cases serial observations were made. Excluding children and five severely dehydrated adults, the average in 33 cases was 32 mg. per 100 c.cm. In the five adults the figures were 157, 79, 63, 67, and 70 mg. respectively.

Sedimentation Rates.—During May and June, when other haematological observations were being made, it was repeatedly observed that blood samples sedimented very rapidly. The sedimentation rate was recorded in 28 cases between June 7 and July 6 and was increased in every one, the drop varying from 22 to 69 mm. in one hour, with an average fall of 53 mm. In 12 of these patients who were radiologically free from tuberculosis the average sedimentation rate was 49 mm. in one hour, and in 7 of the 12 we had probably not had recent typhus (Weil-Felix reactions negative in all dilutions, 2 positive in 1 in 8% but not higher); the average was 45 mm. in one hour. The average haematocrit reading of these seven cases was 35.0 and the average serum protein 6.7 g.%. It appears, therefore, that a rapid sedimentation rate is characteristic of starvation cases whether or not infection is present, and that the main cause of this increase in rate is not simply the anaemia of starvation.

Serial Blood Examinations.—Great difficulty was encountered in following up patients, because as soon as they were well enough they were liable to be moved to other camps or to be evacuated from Belsen to their native lands. However, serial observations over periods ranging from 9 days to 45 days were made on 22 patients, and some evidence was obtained that recovery from the anaemia did not depend on the administration of liver or iron. For instance, in three patients who were closely observed and were known to have had no medicine or injections and to have received simply the ordinary diet, the changes in the blood were as follows.

Case	Date	R.B.C.	Hb (%)	Hmt (%)
M 2	May 14	2,790,000	57	25.5
	June 9	3,920,000	51	37.6
M 8	May 31	4,010,000	65	32.0
	July 7	4,650,000	76	35.6
M 15	May 30	2,610,000	51	24.6
	June 21	3,640,000	66	36.8

These rates of recovery were greater than those observed in many of the other cases, and some patients showed a very slow rate of improvement, with some tendency of the rate of increase in haemoglobin value to lag behind the increase in red cell count. Very few of the tuberculous patients showed any increase in values, and a few became more anaemic while under observation.

Serial Observations on Serum Proteins.—Between six and ten weeks after the initial liberation of the camp serial observations on serum protein concentration were made in 16 cases over periods extending from 12 to 45 days (average, 23 days). In 11 cases an increase of between 0.8 g. and 3.3 g. % was observed (average, 1.7 g. %). In 5 other cases changes from a fall of 0.2 g. % to a gain of 0.4 g. % were found. In three of these the period of observation was short (12 to 15 days), but in two the period was 37 days. These two patients were non-tuberculous; one had no diarrhoea and the other only very slight diarrhoea. The failure of the serum protein to show an appreciable increase in these two is attributed primarily to a poor intake, since both had indifferent appetites and ate but little. It is of interest that as late as seven weeks after the liberation (that is to say, the first week in June)

none of the 16 cases appeared to have reached their maximum serum protein concentration, since even cases which had by this time reached figures within the normal range showed a further increase subsequently.

Urinary Examinations.—In the majority of starvation cases examined no abnormalities were found in the urine. However, in the remainder two features occurred unduly frequently. First, urinary infections were found in five out of 21 cases taken at random; secondly, evidence of subacute nephritis was present in six out of 14 cases of persistent oedema examined about two months after the liberation of the camp. The most likely cause of this nephritis seems to be typhus.

Renal Function

From the evidence of the estimations of blood urea alone it may be concluded that there is no gross disturbance of renal function in cases of starvation, except in so far as extrarenal azotaemia occurs when there is severe dehydration.

Evidence of a normal glomerular filtration rate in emaciated patients was obtained by estimating the inulin clearance in two female subjects who had lost 36% and 37% of their body weight respectively. The actual inulin clearances observed were within normal limits (see Table V), and when corrected for surface

thus appears that in at least some cases of "hunger oedema" which clear up slowly there is an impairment of renal function, although the cause of this is not known.

Inulin and diodone clearances were carried out in two patients who had been diagnosed as cases of nephritis. Very low clearances were found in both instances.

[In estimating inulin and diodone clearances the routine followed did not differ in any essential from that described by Smith (1943) and co-workers (Goldring *et al.*, 1940). Inulin was estimated by an unpublished method of Dr. S. W. Cole, and diodone by Alpert's (1941) method.]

Summary

Observations were made on Central European subjects, of both sexes, who had survived conditions of very severe starvation. The average loss of body weight in a group which included some of the less severely affected cases was 39%, and in individual cases the loss was as great as, or slightly greater than, 50% of the original weight. The majority of the patients had recently had typhus, and in one group examined 40% had pulmonary tuberculosis.

All subjects examined were anaemic, the average Hb value in 30 males being 62.5% (9.8 g.%), and in 23 females 57.3% (8.9 g.%); children were similarly affected. In all cases the type of anaemia

* From Smith (1943). † Weight after loss of most of oedema fluid.

(N.B.—Figures are based on the average of three clearance periods in those cases in which only the inulin clearance (C_{IN}) and the diodone clearance (C_D) were measured. When the maximal secretory power of the tubules for diodone (T_{MD}) was also measured, C_D is based on two periods, T_{MD} on two periods, and C_{IN} on four.)

area were slightly higher than the normal average. The renal plasma flow, as estimated by the diodone clearance, was normal in one case but reduced in the other. It is possible that in the latter case apprehension was responsible, since the patient was rather restless throughout the test. In any event, the maximum secretory power of the tubules in this case, as measured by the diodone excretion at a saturation level, was normal. In both these patients blood pressure was low, and it is of interest that renal function was still normal when, as in the first case, the pressure was approximately 88/58.

Inulin and diodone clearances were also measured in two patients with severe generalized oedema. One of these patients was of great interest from several points of view. She had very swollen face, swollen arms, ascites, oedema of the back, and gross oedema of the legs and feet. Her urine was tested repeatedly and never contained albumin. Her blood pressure was 90/60; there was no dyspnoea or engorgement of the veins. Her serum protein concentration when she was first seen on June 29 was 4.2 g.%. Although there was thus evidence of considerable protein deficiency she had retained quite a large amount of her body fat, as was discovered when "cutting down" to expose a vein. While she was still in this very oedematous condition her renal function was estimated. The inulin clearance was only 66 c.cm./min. and the diodone clearance 182 c.cm./min. Even if these figures are corrected for surface area, using the weight to which the patient was reduced after the loss of most of the oedema fluid, they are still below normal (inulin 80 c.cm./min., diodone 230 c.cm./min.).

The second case of gross oedema with hypoproteinaemia (serum protein 4.0 g.%) but without albuminuria gave similar results. This patient died shortly afterwards, and it was thus possible to examine kidney sections. The only histological change was a slight desquamation of tubular epithelium. It

was the same—namely, normocytic and normochromic—indicating a reduction in the total output of erythrocytes from the marrow rather than any interference with maturation. There was little difference in haemoglobin values between tuberculous and non-tuberculous subjects, indicating that tuberculosis was not the chief cause of this anaemia. In uncomplicated cases, recovery from anaemia proceeded satisfactorily with ordinary feeding and without the addition of liver or iron to the diet.

Total serum proteins were reduced to an average figure of 5.1 g per 100 c.cm. (normal British soldiers, 6.7 g. per 100 c.cm.). There was a correlation between the degree of oedema and the total serum protein levels when averages were compared, although in individual cases there was some overlap. The serum protein levels in individual cases were not correlated with Hb levels. The return of serum protein concentrations to normal was slow, and on the average was still incomplete two months after the camp was liberated.

Blood volume was reduced, but to a less extent proportionately than body weight. In oedematous subjects the blood volume tended to be lower relative to the total body weight.

There was no evidence of any interference with renal function in severely starved non-oedematous patients, apart from cases complicated by dehydration. However, two subjects with gross oedema (severe hypoproteinaemia; no albuminuria) showed considerably reduced clearances of inulin and diodone.

Starving patients are fastidious about their food, and it does not suffice to provide a diet which merely satisfies theoretical nutritional requirements.

D.B.E.: A NEW SYNTHETIC OESTROGEN

BY

RAYMOND GREENE, M.A., D.M., MRCP.

Temporary Physician the Metropolitan Hospital Physician Tindal
House Emergency Hospital Aylesbury

Robson and Schonberg reported in 1942 the synthesis of the pro-oestrogen α -di (p ethoxyphenyl) β phenyl bromoethylene the formula of which is

This substance known as DBE is absorbed from the alimentary tract but differs from other orally active oestrogens in having a prolonged action whether it is given by mouth or by injection. By experiments with oophorectomized mice Robson and Schonberg showed that DBE has an oral threshold similar to that of oestradiol and much higher than that of stilboestrol. Its action differs from those of oestradiol and stilboestrol in that a small increase in the dose produces a great prolongation of action. It appears therefore, that DBE is stored in the body and slowly released. The main site of storage was shown to be the fat (Robson and Ansari 1943) substantial amounts being present in the body fat of mice a fortnight after administration, by which time it has been eliminated from other tissues.

At first sight it seemed doubtful whether such a substance would be of more than academic interest. Further consideration suggested the possibility that in certain menopausal patients who are liable to hypochondriasis some psychological advantage might be obtained by the administration of a drug at say, weekly intervals rather than several times a day or even daily. It was therefore decided to investigate the effects in women complaining of severe menopausal symptoms. Such patients are especially suitable for trials of oestrogenic substances for the effects may be numerically, if roughly, gauged by the number of "flushes" and more exactly by the examination of vaginal smears. During the trial three cases of carcinoma of the prostate became available and it was hoped that in these the level of serum acid phosphatase might act as a numerical expression of oestrogenic effect. Unfortunately the shortage of staff in pathological laboratories at present made it impossible to carry out this plan completely. The effects were examined also in three cases of uterine atrophy.

Menopausal Patients

Six patients were chosen in whom the only menopausal symptoms were hot flushes. They were all women whose general demeanour and past history suggested that they were mentally stable. It is of interest in this connexion that one patient not included in the series was entirely unrelieved by DBE and by stilboestrol but was completely cured by phenobarbitone.

Each patient was given an inert tablet for a month before the trial and the daily flushes were counted. The daily average was in no case significantly affected by "dummy" treatment.

Case 1—Average in the control period 20 flushes a day. Preliminary experiments with doses of from 0.1 g and upwards showed that clear cut results were not obtained with a single dose of less than 1 g. A dose of 1 g was followed four days later by a steady fall in the number of flushes the improvement reaching a maximum in a fortnight. A maintenance dose of 300 mg weekly kept the flushes at the intended level of about 4 a day. Of late, on the same dose, they have averaged 2 a day.

Case 2—Average in the control period 22 flushes a day. Preliminary experiments with doses of from 0.5 g and upwards showed that satisfactory results were not obtained with a single dose of less than 1 g. This dose was followed by an immediate fall to an average of 3 flushes a day, which was maintained for 3 weeks. A maintenance dose of 300 mg weekly maintained the flushes at an average of 5 or 6 a day, though an occasional additional loading dose has been needed.

Case 3—Average before treatment, 18 flushes a day. The effect of a single dose of 1 g was studied. The improvement was not

evident until the beginning of the second week, but continued steadily for 6 weeks, when a sudden deterioration occurred. Daily vaginal smears showed an improvement, beginning on the sixth day. They became normal on the eighth day, and despite continued flushes remained substantially normal until the clinical deterioration set in this deterioration being "mirrored" by the histological appearances. The deterioration was stopped by 500 mg. and maintenance dose of 300 mg has been needed.

Case 4—This patient had originally been treated successfully with another oestrogen and had relapsed after cessation of treatment. She was having about 4 flushes a day. One gramme of DBE was given. An improvement began in a few days and with a maintenance dose of 200 mg weekly, flushes entirely disappeared in 10 days. When the maintenance dose was reduced to 100 mg the flushes gradually reappeared in the succeeding fortnight.

Case 5—Before treatment this patient had only 2 or 3 flushes a day but was greatly disturbed at night, when the flushes usually occurred 4 times and at the worst were almost continuous. She was given 1 g of DBE with no maintenance dose. Improvement began in 3 days and in the second week the flushes averaged 2 in the 24 hours. This state was maintained for a further 6 months when a gradual deterioration set in. The loading dose was repeated and she has remained well on a maintenance dose of 200 mg weekly.

Case 6—Before treatment she had 12 flushes a day. A dose of 1 g of DBE gradually reduced her flushes. After 3 weeks they averaged 1 or 2 a day. On a maintenance dose of 200 mg weekly they ceased altogether, but when this was reduced to 100 mg they reverted in a month to 6 or 7 a day.

Cases of Carcinoma of the Prostate

Case 7—Aged 76. Admitted to hospital under Mr R. H. Gardiner complaining of symptoms of prostatic enlargement for over a month. The prostate seemed to be benign. The vasa were tied and a suprapubic cystostomy performed on Oct. 5, 1943. He was discharged and readmitted for the second operation. Cystostomy on Jan. 21, 1944, disclosed that the prostate was malignant and inoperable. He was transferred to a medical ward, where further investigation failed to reveal the presence of metastases. The serum acid phosphatase was 30 units per 100 ccm. He was given 1 g of DBE. The S.A.P. was re-estimated by Dr Douglas Robertson at frequent intervals until April, 1944, when shortage of staff made a continuation impossible. During this time he received no additional DBE as it was hoped that the biochemical estimations would indicate the necessary frequency of administration. He began to micturate per urethram, the suprapubic opening closed, and he was discharged in good order on March 8, 1944. When it became impossible to continue the frequent S.A.P. estimations he was given 1 g of DBE and a weekly maintenance dose of 200 mg. He remained well until Jan., 1945, when he began to have dysuria and frequency of micturition with occasional incontinence. The symptoms increased in severity and he was readmitted on Feb. 20. There was no change in his clinical condition and x-rays still failed to show any metastases. His S.A.P. had however risen to 144 units. His urine was grossly infected with *B. coli*. When this had been treated he became symptom free and insisted on going home. Meanwhile he was given 3 g of DBE with a maintenance dose of 0.5 g weekly. The S.A.P. dropped only to 120 units and thereafter rose again. The maintenance dose was then increased to 1 g weekly but with little effect. On June 8 a change was made to 5 mg of stilboestrol three times a day. On July 2 the S.A.P. was 43 units per 100 ccm.

Case 8—Aged 70. This patient was admitted on June 16, 1942, with the symptoms of enlarged prostate. Carcinoma was suspected for he had severe pain in the lower part of the back and in the thighs. The x-rays showed osteoarthritis only and the S.A.P. was 0.9 unit. The prostate was enucleated by Mr Gardiner and was found by Dr R. W. Searf to show an area of epithelial-celled carcinoma. He was given 1 g of DBE with a maintenance dose of 200 mg weekly, and has remained free from prostatic symptoms since. X-rays show no secondaries and the S.A.P. has remained normal.

Case 9—Aged 51. The patient was under treatment for post-operative pneumonia following appendicectomy. There had been no symptoms of prostatic enlargement before his admission but while in bed in hospital he began to have slight difficulty in beginning micturition and to complain of backache which rapidly became very severe. The prostate did not seem to be enlarged but it was hard. X-rays showed extensive secondaries in the pelvis, sacrum, lower lumbar vertebrae and ribs. The S.A.P. was 462 units. Treatment was begun with 1 g of DBE. Relief from pain was satisfactory for a day or two after each dose, but gradually increasing doses up to 5 g weekly failed to prevent a steady rise in the S.A.P. After seven weeks it had risen to 105 units. DBE was stopped and 5 mg of stilboestrol t.d.s. given instead. The S.A.P. fell to 89 units in three weeks.

Patients with Uterine Atrophy

Case 10.—Her periods began at 14 and occurred regularly for 3 days at intervals of 30 days until the birth of a child at the age of 23. After 10 months of lactation, menstruation was again normal for three years. It then ceased, and had not occurred for 17 months before her first attendance. The uterus was found to be very small. Treatment with D.B.E. was begun, but soon afterwards she received serious injuries in an air raid and was lost to view. In Oct., 1944, treatment was begun again with 1 g. of D.B.E. and a weekly maintenance dose of 200 mg. Treatment for 5 months produced neither menstruation nor increase in size of the uterus.

Case 11.—Since the menarche began at 14 the periods had occurred at irregular intervals of 2 to 6 months. The uterus was minute and the physical make-up suggested hypogonadism. A loading dose of 1 g. of D.B.E. with a maintenance dose of 200 mg. weekly produced no change in three months. During the succeeding three months she was given 5 mg. of oestradiol benzoate intramuscularly twice weekly. The uterus increased in size and menstruation occurred more frequently. A change to oestradiol benzoate, 5 mg. twice weekly during the first fortnight only of the intermenstruum, produced regular menstruation, which has been maintained less regularly since cessation of treatment.

Case 12.—This patient complained of dysmenorrhoea. The menarche had begun at 11 and menstruation had occurred for 5 days every 21 to 56 days. It was very scanty. The uterus was minute. During a period of a year a total of 12 g. of D.B.E. was given. Her menstruation became distinctly more regular (3-4/28-33), but the dysmenorrhoea was not relieved and the size of the uterus was only doubtfully increased.

Toxic Effects

D.B.E. is of very low toxicity. Two menopausal patients treated with the substance felt sleepy on the day after each administration. The symptom was not regarded as serious by the patients, and was mentioned only in answer to a leading question. Lassitude occurs occasionally during the administration of other oestrogens. Only one patient complained of nausea. This symptom occurred on the same day as the administration of the loading dose, and was not severe. The patient who received 5 g. a week had no unpleasant symptoms. Uterine bleeding, leucorrhoea, and headache were not reported.

Discussion

It is clear from the results obtained in six patients suffering from the vasomotor symptoms of the climacteric that D.B.E. given orally is an effective oestrogen with a prolonged action. A loading dose of 1 or 2 g. brought relief of symptoms for two or three weeks. The good effects can be maintained by a weekly dose of 100 to 300 mg.

Less satisfactory results were obtained in three cases of uterine atrophy; but little can be learned from this, for the response of this condition to other oestrogens is very uncertain. D.B.E. failed in carcinoma of the prostate. One of the three patients has remained well for three years, but his prostate was removed at so early a stage of the disease that it is possible to ascribe his good health to the operation rather than to the medical treatment. The other two patients showed no significant improvement under treatment with D.B.E., but responded dramatically to stilboestrol.

This failure may be due to insufficient dosage. It is possible to judge this question by two criteria—comparison with stilboestrol or comparison between the two classes of patient. It is difficult to compare the effective dose of two oestrogens which are absorbed and destroyed or excreted at different rates. Judging from mouse experiments (Robson, personal communication) it would seem that from 20 to 50 times as much D.B.E. is required to produce the same effect as stilboestrol, but allowance must be made for species differences. Taking this figure with reservations, it would appear that at the time of maximum dosage one patient with carcinoma of the prostate was having the equivalent of 80 to 200 mg. of stilboestrol a week and the other 200 to 500 mg. Both responded dramatically to about 100 mg. of stilboestrol weekly. Moreover, one was given about four times and one about ten times the amount required to relieve menopausal symptoms and to change the vaginal smear. It must be remembered that some menopausal women are relieved by extremely small doses of oestrogens, but, taking the two criteria together, it seems unlikely that the dose was too low in the carcinoma cases. The possibility should be borne in mind that there may be a sex difference in the rates of absorption of oestrogens, so that a dose sufficient to treat

a woman may be insufficient for a man. No data on this question seem to exist. It should also be remembered that D.B.E. is not strictly an oestrogen but a pro-oestrogen, and that pro-oestrogens may be less effective than oestrogens in the control of carcinoma. The oestrogenic effect of a pro-oestrogen depends not only on the dose but on the rate of its conversion into an oestrogen. An increase in the dose beyond the amount which can be converted by the body would not produce any increase in the oestrogenic effect. It may well be that the body is capable of converting from pro-oestrogen to oestrogen a sufficient amount to deal with menopausal symptoms, but not enough to control carcinoma of the prostate, which probably demands a higher oestrogenic level. Robson (personal communication) has found that the administration of large doses of D.B.E. to oophorectomized mice does not induce mating, whereas large doses of oestrogens (for example, oestradiol and triphenyl-chloroethylene) do so. Since the oestrogenic level necessary to induce mating is about 200 times that necessary to produce vaginal cornification, it seems probable that in this experiment the D.B.E. was not converted into an oestrogen at a sufficient rate to produce the concentration necessary for mating. A similar failure may be the explanation of the ineffectiveness of D.B.E. in controlling carcinoma of the prostate.

D.B.E. is a substance of great theoretical interest, but in some respects it is inferior to the other synthetic oestrogens, and it is doubtful whether the advantage of weekly over thrice-daily administration is sufficient to warrant the general introduction of yet another.

I would like to express my gratitude to Prof. McIntosh, Dr. Douglas Robertson, Dr. John Murray, and Mr. R. H. Gardiner for their collaboration, and to Dr. A. N. Macbeth, of Organon Laboratories, for supplies of D.B.E.

D.B.E. IN TREATMENT OF MENOPAUSAL SYMPTOMS

BY

STANLEY WAY, M.R.C.O.G.

Assistant in the Department of Obstetrics and Gynaecology, the Medical School, King's College, Newcastle-upon-Tyne

The chemical and pharmacological properties of this new synthetic oestrogen are summarized in the accompanying paper by Dr. Raymond Greene. The aims of the work described in that paper were: (1) to confirm that the prolonged action of D.B.E. occurs in the human subject; and (2) to establish a dosage suitable for clinical use.

My own aspect of the work has been confined to patients suffering from symptoms due to the premature cessation of ovarian function brought about by surgical and radiological means. Some degree of selection was used in choosing the subjects. This was done as follows. Twenty-five case records were selected at random—7 of these were discarded as they were not experiencing menopausal symptoms at the time; 4 were rejected because they lived more than 20 miles from Newcastle and it was felt that they might not attend regularly on this account.

Fourteen attended, and were offered treatment for their "hot flushes." No previous therapy with oestrogens had been given to any of them. For the first four weeks these patients were treated with inert tablets consisting either of 15 gr. (1 g.) of cane sugar or of 10 gr. (0.65 g.) of household flour coated with chocolate. On a chart provided for the purpose they kept a record of the number of flushes experienced. Three of the patients were relieved by these tablets and were dropped from the series.

The remaining 11 had no relief, and the weekly total of flushes remained constant. 10 patients were given an initial dose of 1 g. D.B.E. and one severe case received an initial dose of 2 g. 8 of the 11 had some reduction in the number of flushes one week after the administration, but only in two mild cases was the response pronounced. One of these, which

had been averaging 20 flushes a week, dropped to nil in two weeks, and this improvement was maintained for another two weeks without further treatment. Thereafter the flushes began to return. A dose of 2 g. brought about a marked improvement in 9 patients, and this effect lasted on an average three weeks without further administration. After this time the number of flushes increased again.

The next problem was that of a maintenance dose. This varied according to the severity of the symptoms, and it was eventually found that 0.2 g. per week was satisfactory. In this series it was administered in doses of 0.4 g. fortnightly. It was also found that if more than three weeks was allowed to elapse between the administrations it was advisable to give another initial dose. Increase of the maintenance dose was not satisfactory. Some of the side-effects of other synthetic oestrogens were observed. Four patients vomited after receiving 2 g. This started about 8 hours after taking the tablets, and continued for 36 hours. One of these patients had nausea but no vomiting after a small dose. Three others did not actually vomit but were nauseated by large doses. This began about 24 hours after taking the tablets and continued for some three days. Three patients had uterine bleeding or a brown discharge lasting for several days. In two this occurred two weeks after the last administration, and in one immediately after taking a large dose. Two other patients had severe uterine colic following a dose of 2 g., and one of these developed a white vaginal discharge which was found to be due to the excessive secretion of mucus from the cervical glands. Five patients experienced headache for 24 hours after a large dose; they had not previously suffered from headache. In those cases in which headache was a prominent feature of the menopausal syndrome it was relieved by D.B.E. Four patients complained of lassitude during the course of the treatment. Although this symptom does not appear to be generally recognized as an effect of synthetic oestrogens I have found that it frequently occurs in patients receiving stilboestrol. Most of these effects occurred only when large doses were given.

Results

Of the 11 cases 5 were completely relieved of their symptoms; 3 were greatly improved, and the average reduction in the weekly number of flushes in these patients was from 80 to 6. The remaining 3 patients failed to respond at all even after doses of 3 g.

The 3 who were improved but not completely relieved were put on to stilboestrol 1 mg. t.d.s. This brought about complete relief in all cases. Two of the three failures were similarly treated and were also completely relieved within three weeks of starting stilboestrol therapy. The third patient in this group suffered from disseminated sclerosis and failed to attend again. One of the patients had a severe leucoplakic vulvitis which did not improve on the doses given and has subsequently undergone vulvectomy.

Summary

D.B.E. (o-o-di-(p-ethoxyphenyl)- β -phenyl bromoethylene) is a synthetic oestrogen with a prolonged action.

This substance was used to relieve menopausal symptoms in 11 patients who had undergone surgical or radiological castration; 5 were completely relieved, 3 greatly relieved, and 3 showed no response.

The dosage required for the relief of these symptoms is an initial dose of 2 g. followed by a maintenance dose of 0.2 g. weekly. Mild cases may require only half this dosage.

The side-effects of other synthetic oestrogens have been noticed with D.B.E.

It appears from this small series that D.B.E. is probably not as effective as stilboestrol in the relief of menopausal symptoms.

It is probable that its sole advantage is that it needs to be administered infrequently and not daily as with other synthetic estrogens.

I should like to thank Dr. A. N. Macbeth for her help and advice, and Organon Laboratories Ltd. for the supplies of D.B.E. used in his investigation.

A. H. Williams (*Delaware State med. J.*, 1945, 17, 179) records a case of myelitis following chicken-pox in a boy aged 4. Recovery took place without specific therapy.

CONCENTRATING MALARIA PARASITES IN THIN FILMS

BY

K. B. ROGERS, M.B., B.S.

Area Pathological Laboratory, Spooley Bridge

The diagnosis of malarial infection has often to be made on samples provided by practitioners, and the pathologist frequently finds fault with the smears provided—usually, because they are too thick, are unevenly spread, and are allowed to dry too slowly.

The thick-film technique is widely employed to give concentrated films, but the parasites are not intracellular and many pathologists do not like them. Wilcox (1942), in her monograph, describes the thick-smear technique very clearly, but obviously it is one that only the trained laboratory worker can employ; she states that the thin film is ideal for demonstrating the morphology of the individual parasites. Figures are given for the degree of concentration obtained by many authors using the thick-smear method; these vary from 10 to 50 times. Todd and Sandford (1943) quote the method of Bass and Johnson as described it is very laborious, but it does provide concentrated intracellular parasites.

There will be many cases of malarial relapse in the next few years, and it is hoped that the following technique may be of help in proving if such cases are suffering from a genuine relapse; the proof may be of great importance in the granting of a pension for the patient. The technique was evolved to secure the advantage of concentration as well as that of seeing intracellular parasites; it allows a practitioner to obtain the blood samples, using the technique he employs for obtaining blood for a Wassermann reaction and saves making blood smears.

Technique

Any blood may be used, but, if the blood has clotted, many of the white cells and all the platelets are avoided, making the slide easier to examine. When clotted blood is employed it is shaken and the serum drawn off and centrifuged for 2 to 3 minutes in a small tube; the serum is discarded. Except for a volume approximately equal to that of packed red cells. The residual serum and the red cells are mixed, and this blood is run into a capillary tube, the end of the capillary is sealed and the tube centrifuged hard (2000 to 3000 revolutions per minute) for 20 to 30 minutes.

The capillary is removed and a scratch made with a glass-cutter or diamond, about 1/8 in (0.32 cm) above the top of the packed red cells; the tube is held horizontally, and is broken at this mark. A second cut is made about 1/8 in below the top of the red-cell layer; the tube is again held horizontally, and is now broken at this second mark. The tube is held horizontally after the first cut to prevent the plasma running down over the operator's fingers, and, after the second, to prevent any loss of the contents of the wanted specimen.

The next stage was evolved to allow easy handling and mixing of the contents of this small segment of the capillary tube. The butt end of a Pasteur pipette, where it starts to narrow down, is heated in a Bunsen burner flame, and when soft the two extremities of the pipette are pressed towards each other, allowing the tube to bend into an S shape. The pipette is again heated in the Bunsen burner flame about 1 in. (2.5 cm) from this bend; it is drawn out and sealed taking care to make the terminal portion thin. If the end is not thin it is difficult to break off the tip later, and some of the specimen will be lost. The short piece of capillary tube is dropped into this prepared pipette with serum uppermost; the tube is then placed in the centrifuge, which is switched on for from 2 to 5 seconds. The blood is now in the capillary end of the pipette; the thinned tip of the pipette is cut off, a test is applied to the butt, and the blood is blown out on to a slide and a thin smear made. Alternatively, the blood is mixed on a wax slide. The edges of the film are examined for the parasites. The accompanying figure shows the completed slide.

Results

The degree of concentration has been estimated by counting the number of parasites seen, under the 1/12 objective, in an equal number of fields, usually 100, in both the plain and the concentrated films. In the last 22 positive bloods the average degree of concentration has been $\times 15.8$ —made up of 426 parasites in the plain, as against 6,718 in the concentrated films. The concentration has varied from $\times 5$ to $\times 56$. Eleven of these lay between $\times 10$ and $\times 24$; others were $\times 5$, $\times 6$ (twice), and $\times 9$. There were also specimens with $\times 56$, $\times 50$, $\times 35$, and $\times 33$ concentration. In a total of 52 positive bloods examined 5 were positive in the concentrated films only. These figures would seem to compare favourably with those obtained in the thick-smear method. Schüffner granules do not appear to stain well in the concentrated preparations made by me.

Since the technique was evolved only two cases of falciparum infection have been concentrated. The first was diagnosed as an M.T. infection on a thin smear provided on July 20, 1945; the hospital was informed by telephone and warned to apply intensive therapy, as a heavy infection with trophozoites was present. The patient had the following treatment:

July 20: 9 g. intramuscular quinine.

July 21: Mepacrine t.d.s.

July 22: Morning—mepacrine, 2 doses. Patient went into coma at midday. Afternoon—9 g. intravenous quinine.

July 23, 24, and 25: Mepacrine t.d.s.

On July 25 venous blood and thin smears were obtained and were sent by post to the laboratory; 7 gametocytes in 500 fields were seen in concentrated smears made on July 26; but several pathologists have failed to find parasites in the thin smears provided.

The other M.T. infection was a fatal case of gastro-intestinal and cerebral malaria (which it is hoped may be described in detail later). 1½-day-old blood, taken for a Widal test 18 hours before death, was used to provide the red cells; unconcentrated smears showed a very heavy infection with trophozoites (1 in every 3 of the red cells were infected). With such a heavy infection, it is hard to demonstrate concentration, but the concentrated smears showed parasites in 2 out of every 3 red cells, and also demonstrated gametocytes and schizonts which were not seen in the plain smears.

Evidence of concentration of crescents based on two cases is not sufficient, and I would be grateful for both thin smears and venous blood samples from proved cases of M.T. infection, as I would like to use the method on more such cases.

Other Possible Uses for the Method

The method described has been used several times to concentrate the nucleated cells in marrow obtained by sternal puncture, to facilitate the search for Leishman-Donovan bodies. The marrow was placed in a tube containing dried heparin (the mononuclears tend to pick up the crystals of Wintrobe's oxalate mixture, so this could not be employed). Very good concentration of the nucleated cells was obtained, but no L.D. bodies were seen; in whole blood heparin often causes agglutination of the white cells; but, even after two hours and the centrifuging in capillaries, there was no tendency for the cells to clump in these sternal-marrow specimens. It may be that the technique could be used for the diagnosis, on stained smears, of other protozoal and spirochaetal infections, but I have not had the opportunity of trying it.

I would like to express my thanks to Sir Philip Manson-Bahr for his encouragement and advice, to Dr. C. M. Wenyon for his helpful criticisms, and to the Regional Adviser in Pathology, Prof. Bernard Shaw.

Medical Memoranda

Immunity to Sandfly Fever

In a previous article (Cullinan and Whittaker, *Journal*, 1943, 2, 543) an outbreak of sandfly fever in two adjoining hospitals in the Middle East, occurring in the summer of 1942, was described. In that outbreak most of the N.C.O.s and men of the staffs of the two hospitals and, later, large numbers of patients admitted for other diseases to Hospital A were attacked (Hospital B was not at first functioning). In the summer of 1943 sandfly fever was rampant in the surrounding district, and close on 1,000 patients suffering from the disease were admitted to Hospital A from outside (Hospital B had now left). Inside the hospital, however, far fewer members of the staff and patients admitted for other diseases were affected. This lower morbidity within the unit may have been related to improvements in the camp site. Measures for "control" were the same in both years.

In 1942 both hospitals were newcomers to the district. Although Hospital A had been in the Middle East for a considerable time, it had come from an area where sandfly fever was unknown. Hospital B had recently arrived from the United Kingdom. In the 1942 outbreak it was recorded that 15% of the N.C.O.s and men had two and sometimes three attacks of sandfly fever at intervals ranging from 2 to 12 weeks during the period of the epidemic. Moreover, it was obvious that these later attacks were not relapses but were caused by reinfection. This suggested that one attack of sandfly fever conferred little or no early immunity, or that, if it did, it was remarkably short-lived.

In the 1943 outbreak, however, there was evidence that an attack of sandfly fever might confer a more distant immunity. During the time of this outbreak the average daily strength of N.C.O.s and men in Hospital A was 240. Between June 1 and Sept. 30, while 55 of the 142 who had not been with the unit in the previous summer caught sandfly fever, only 13 of the 98 who had been with the unit during both summers were affected. In other words, the disease was roughly three times less common among those who had been present in the 1942 epidemic than among those who had not.

The evidence suggests that while an attack of sandfly fever does not confer an early immunity, or that if it does it is short-lived, it may confer a more distant immunity.

Frontal Lobe Abscess Treated with Penicillin

Spreading acute osteomyelitis of the frontal bone is a well-recognized complication of frontal sinus suppuration and carries a high mortality. When complicated by a frontal lobe abscess the prognosis is well-nigh hopeless. The following case illustrates, I think, not only the efficacy of penicillin in this condition but also the necessity for adequate surgery if treatment is to be successful.

CASE RECORD

A boy aged 16 was admitted to hospital on May 14, 1945, with a history of frontal and occipital headache, vomiting, and restlessness of a week's duration. There was no history of trauma. Temperature 101.6°, pulse 90 a minute. There was a red fluctuant swelling overlying both frontal sinuses, but no nasal discharge. A diagnosis of frontal sinus empyema was made, and this was confirmed by skiagrams. On the 16th both sinuses were drained externally and thick offensive pus evacuated. It contained *Staph. aureus* and diphtheroids which were 100% penicillin-sensitive. On May 31, in spite of good drainage and sulphathiazole in full doses, the boy became drowsy and irritable, and a spreading diffuse oedema of the frontal region extending backwards was now evident. On June 1 he became semiconscious and his temperature fell to 96° F. and pulse to 48. The right pupil became widely dilated and fixed, while the left pupil remained contracted. On June 2, under local analgesia, supplemented by chloroform on an open mask, a large semicircular flap was turned down over the frontal region. There was widespread necrosis of bone with some loose sequestra. All necrosed bone was removed, and a sinus was found in the anterior aspect of the right frontal lobe through which pus flowed out under tension. This sinus was utilized later for the insertion of a small rubber drainage-tube which was sutured to the dura. Several ounces of pus were aspirated from the abscess cavity. On June 4 penicillin therapy was begun, 2 c.cm. (123,500 units) being injected intramuscularly every 3 hours for a period of 10 days and 6 c.cm. instilled into the abscess cavity twice daily for 5 days. Rapid improvement was soon manifest, and the drain was removed after 3 weeks. The frontal sinuses, however, continued to drain, and on July 9 they were again exposed by an upturned flap and multiple poly-

removed from both sides. On July 30 all the wounds were dry and he was allowed up. No obvious change for the worse had occurred in his mental condition. X-rays of the skull revealed a gap in the frontal bone measuring 3 in by 2 in (7.5 x 5 cm). It is proposed to close this gap by a bone graft at a later date.

Surgeon, Municipal General Hospital
Barnley

A Case of Locked Twins

This note on a case of locked twins is offered in the belief that all such cases should be reported to assist future compilations.

CASE HISTORY

Mrs. A., aged 23, a para-1 gravida 2, was admitted to Dilston Hall Maternity Hospital at 6 a.m. on April 17, 1944. The patient was at full term by dates and had been in labour for about two hours. On admission the fact of labour was confirmed, and her case was diagnosed as a singleton breech presentation with membranes ruptured. At 8.40 a.m. the day-staff labour ward sister first saw her, and on separating the labia she noted (a) two small feet presenting which from their size she diagnosed as belonging to a twin, and (b) a short loop of prolapsed cord which was thin and almost pulseless. She called me, and I was available in a matter of minutes.

I found the patient in the lithotomy position ready for delivery with both feet protruding from the vulva and a 5-in (12.5-cm) loop of cord with them. The feet showed signs of life. The cord was not palpated. The cervix was fully dilated and withdrawn. The feet, knees, and breech were extracted and delivery was made as far as the umbilicus. Progress then ceased. Chloroform induction was begun, but before anaesthesia was established I was able to reach up on the maternal left side of the pelvis and feel a vertex about 1 in (2.5 cm) above the level of the ischial spine of that side. While the uterus was relaxed it was easy to push back this vertex, using two fingers only, and to secure the posterior arm of the leading twin. The anterior arm was then freed. The first twin was then easily delivered by extension-traction, using the left hand, while two fingers of the right hand were employed in holding back the second vertex above the brim of the pelvis.

The first twin was "shocked," but responded to treatment quickly. The second twin was born spontaneously by the vertex ten minutes later. It was in very good condition. The prolapsed cord belonged to the first twin.

The twins were both males and appeared to be uniovular, weighing 4 lb 10 oz (2.1 kg) and 5 lb 3 oz (2.35 kg) respectively. They made normal progress, being discharged on the 22nd day weighing 5 lb 4 oz (2.38 kg) and 5 lb 6 oz (2.44 kg) respectively. The maternal recovery was satisfactory and afebrile.

Interesting points in the above case are the presentations were breech-vertex; the twins were uniovular, both bags of membranes had ruptured spontaneously; early diagnosis was facilitated by the need for medical aid for prolapse of the cord; obstructed labour did not arise; in the easy conditions it was possible to make the required manipulations before anaesthesia was established; and both twins were secured alive.

Late Resident Obstetrician Dilston Hall Maternity
Hospital, Northumberland

Penicillin in Chronic Ear Disease

The persistence of treatment-resistant cases of chronic ear disease in personnel of H.M. ships not only causes despondency in the medical department but debars these men from certain duties, such as those necessitating wearing ear-phones, etc., where they are liable to pass on their infection to the next "watch." Therefore it was decided to treat a number of cases in our ship with local penicillin in the hope of getting better results. Conditions were ideal in that the ship was operating in a temperate climate with normal humidity.

Cases with histories of chronic ear disease each of which had been under treatment for exacerbations of their chronic condition in the ship but were then in a more or less quiescent state, were selected. A careful history of each case was taken, though records of previous examinations and treatment were lacking in several instances. Bacteriological cultures were grown and white cell counts were done before and after the experiment. Those men, whose ears produced growths of organisms which are not sensitive to penicillin, were treated in like manner, as it was considered that they would be useful controls.

TECHNIQUE

Using every possible aseptic precaution including the wearing of sterile gown and mask, a solution of penicillin was prepared by dissolving 100,000 units of penicillin in 64 ccm of sterile distilled water, this was divided equally into four sterile bottles for use on four successive days.

The aural meatuses were carefully mopped out with pledgets, followed by the instillation of 1 ccm of solution (approximately

1,560 units of penicillin). The patient's head was kept tilted for at least five minutes, after which the solution was encouraged to remain in the meatus by the introduction of small sterile gauze wicks. This routine was repeated every twelve hours for four days. Each case thus received 12,500 units of penicillin. In cases with tympanic perforations the solution went in easily enough and did not tend to run out, but in cases with intact drums and narrow meatuses 1 ccm of the solution could be instilled therein only with care and patience. These cases were followed up for two months after treatment.

SUMMARY OF RESULTS

(1) All cases caused by penicillin-sensitive organisms (e.g., *Staph. albus*) were cured. (2) Where mixed infections existed the condition was improved only—leaving the penicillin-resistant bacteria unchanged. (3) Where only penicillin-resistant organisms (e.g., *B. proteus*, *Ps. pyocyanus*, and *M. catarrhalis*, etc.) were demonstrated the condition remained unaltered. (4) Comparatively small doses of penicillin eliminated penicillin-sensitive organisms. (5) The local application of penicillin solution only was tried—insufflation of powdered penicillin might offer an improved technique. (6) The raised white blood cell count returned to normal within two to three weeks in those cases which were cured. (7) It was demonstrated that before treating suppurative otitis the causative organism must be identified, and only those cases which are caused by penicillin-sensitive organisms are worthy of penicillin therapy.

Ether Convulsions with Hyperpyrexia

The following case of ether convulsions is of interest in that the high temperature recorded tends to support the heat-stroke theory of causation. One feels that the conditions under which this operation was performed were such as to produce a rapid rise in the patient's temperature, and as he was already pyrexial at the time of the operation a state of hyperpyrexia was attained, which, with the neurogenic stimuli postulated by Brennan (1941), may have been the precipitating factor in the convulsive attack.

CASE RECORD

The patient, a healthy young soldier, was admitted to the hospital on a sultry evening in Aug., 1943, with acute obstructive appendicitis and symptoms of peritonitis. His temperature on admission was 100° F. The operation was carried out under black-out conditions in an operating theatre of the wooden emergency hospital type the walls of which have considerable heat-retaining properties. The windows were covered with shutters of wall board so that ventilation was almost non-existent. As the operating room communicated freely with the main theatre the latter soon became uncomfortable, warm and humid, and with only one small fan of the suction type, little could be done to control the temperature. The anaesthetic little could be done to control the temperature. The anaesthetic was given with the standard Boyle apparatus a gas oxygen, and ether mixture being used. Macintosh shears were employed as well as towels to shut off the operation area, with the result that as the patient was completely enclosed with the exception of that portion of his face not covered by the anaesthetic mask and the Clausen harness little heat loss was possible.

The operation and anaesthesia proceeded smoothly at first, a gangrenous appendix being removed and a suprapubic drain inserted on account of the large quantity of thin purulent fluid found in the abdomen. The operation had been in progress for about half an hour and the peritoneum had, fortunately, just been closed, when ether convulsions began without warning. The patient's body and limbs were shaken by rapid clonic convulsions of moderate severity.

Owing to the involvement of the muscles of respiration cyanosis rapidly developed, and was only partially relieved by administering pure oxygen and applying artificial respiration. A solution of pentothal was quickly prepared and given intravenously, 3 ccm (0.15 g) being sufficient to stop the convulsions with dramatic suddenness, followed by the resumption of normal respiration.

The wound was now rapidly closed and at the same time the legs were then removed from the patient and rapid sponging of the chest, arms and legs begun, being continued until the temperature was reduced to 103° F., when the patient was returned to the ward. During the night the temperature continued to fall and next morning he appeared to have suffered no ill effects from his ordeal. He proceeded to make a complete recovery.

My thanks are due to the medical superintendent of the hospital for permission to publish this case.

X-RAY DIAGNOSIS OF THE GASTRO-INTESTINAL AND URINARY TRACTS

The Gastro-Intestinal Tract. A Handbook of Roentgen Diagnosis. By Fred Jenner Hodges, B.S., M.D. (Pp. 320; illustrated, 33s.) Chicago: The Year Book Publishers, Inc.; London: H. K. Lewis and Co.

The Urinary Tract. A Handbook of Roentgen Diagnosis. By H. D. Kerr, M.D., and Carl L. Gillies, M.D. (Pp. 320; illustrated, \$5.50 or 33s.) Chicago: The Year Book Publishers, Inc.; London: H. K. Lewis and Co.

When one sits down to write a book on a medical subject it is well to have clearly in mind the object of the book and, in particular, who it is intended shall read it. This may seem to be emphasizing the obvious; it is, none the less, sometimes overlooked by authors. Witness two of the volumes of the "Handbook of Roentgen Diagnosis" series: *The Gastro-Intestinal Tract*, by Fred Jenner Hodges, and *The Urinary Tract*, by H. Dabney Kerr and Carl L. Gillies.

The object avowed in the preface of *The Gastro-Intestinal Tract* is "to present the subject in a manner most useful to physicians who are not and do not intend to become specialists in the field of roentgenology." Immediately after this preface is a 20-page introduction, largely concerned with the technique of examination, with which the physician has little or no concern. The remainder of the book—about 300 pages—consists of an x-ray atlas of the gastro-intestinal tract, with clinical notes of the cases illustrated and brief discussions on x-ray diagnostic signs. Many of these are typical cases, others are comparative rarities, and in some the diagnosis is not known. The last might well be omitted from a book of this size. The illustrations are clear and the paper good. The book will be of interest to clinicians who like atlases (and, curiously, some do: in the hope, perhaps, of finding a short-cut to the knowledge of a specialty).

The Urinary Tract also seems to hesitate about what it sets out to do. The authors' aim has been to produce a "low-priced handbook in which the roentgen appearances of the more common and some of the uncommon lesions are available for ready reference to the student, practitioners, urologists, and radiologist." The English price is 33s., and one can't see many medical students in this country buying it; or radiologists either, for whom it is too elementary to be of real value. A notable omission is the subject of intravenous pyelography. In the several hundred illustrations—very good ones and well produced—there are hardly half a dozen intravenous pyelograms. Indeed, throughout the book the hand (and catheter) of the urologist are much in evidence. But there is no doubt that most readers will find the book of great interest. As an atlas it is of high quality, and the letterpress is clear, straightforward, and very readable; and though the reviewer is not quite clear what the book really aims to do, he enjoyed turning its pages, which is more than he can say of many such volumes.

SETTING UP A RURAL HOSPITAL

Small Community Hospitals. By Henry J. Southmayd, Director, Division of Rural Hospitals, the Commonwealth Fund, and Geddes Smith, Associate, The Commonwealth Fund (Pp. 182. \$2.00 or 11s. 6d.) New York: The Commonwealth Fund; London: Oxford University Press.

In 1925 the *Journal of the American Medical Association* declared that the lack of hospitals was a prominent factor in the increasing trend of doctors away from the countryside. The Commonwealth Fund then offered to meet two-thirds of the cost of building and equipping one or two small hospitals each year in areas where the local community would provide sites, management, and maintenance. During the succeeding twenty years thirteen rural hospitals have been established, and this book deals with the experience thus gained. The questions posed were: What communities should have such hospitals; what areas should a hospital try to serve; who should run and staff them; how can they help their public to get better medical care?

The Fund believes that in helping the establishment of these hospitals it is assisting in the solution of a great national problem because the lack of good medical provision is evidently driving people off the land. Its thesis is that, "If 50-100,000 people will use a single hospital placed at the natural centre of a

homogeneous trading area, they can have about as good a hospital as the same number of people in a single city." The Fund claims that its experience has proved this thesis to hold good. One difficulty has been the fact that an ideal hospital area by no means necessarily conforms to local authority boundaries, and so all the usual local ambitions and traditions have had to be placated. The six chapters in the book deal in a very practical way with all the points which would confront a rural area considering the setting up of a hospital.

One problem which receives a good deal of attention is how to link up these rural hospitals with the consultant facilities commanded by the great city hospitals. On this question reference is made to the experience of our Nuffield Trust and its device of the "key" hospital. The opinion is expressed that hospital co-operation in England has long been "be devilled by the traditional differences between the voluntary and the public institution."

The book ends with the opinion that "in the long run the community will shape the hospital, the health department, and the practice of medicine, to its own purposes, and a great deal of experimentation is going to be needed in the process. The Commonwealth Fund is to be congratulated on a useful contribution to this.

PHYSICAL TRAINING

Médecine, Education physique, et Sports. By Dr. Albert Govaerts. *Actualités Sociales. Nouvelle Série.* (Pp. 162. No price given.) Brussels: Office de Publicité, J. Letégué et Cie, 36, Rue Neuve. 1945.

Dr. Albert Govaerts, the Director of the Physical Training Department in Brussels University, has written on physical education and sport in medicine an attractive contribution to new edition of the "Actualités Sociales," first published between 1904 and 1913. His paragraphs on physical education as builder of health are clearly written in easy (and therefore good) French and show that his reading has been wide and thoughtful. He describes simply and briefly the bearing of the work of a number of physiologists on the problems that "have to be understood by those who set out to train the body, especially during the malleable years of youth. His section on acids is particularly interesting. At the beginning of Chapter IV Dr. Govaerts states: "Among the many aspects of life changed by the profound evolution of which we are actually witnesses . . . the health of the youth of our nation is one that demands our urgent attention." This passage is typical of many in this chapter showing a deep regard and love of his country and of youth in particular. It is indeed charitable of Dr. Govaerts to look upon their ordeal as "an evolution"—as in fact it is. The spirit of study and service to youth shines throughout this small book; but with this is given an interesting number of scientific tables, that should prove helpful to students, of the reactions of the adolescent body. A translation of Dr. Govaerts's book into English should find a wide range of readers not only among medical men concerned directly with physical training, but also among educated medical laymen interested in the youth movement.

PLASTER TECHNIQUE

Plaster of Paris Technique in the Treatment of Fractures and Other Injuries. By Lieut.-Col. T. B. Quigley, M.C. (Pp. 107; illustrated. \$3.50.) New York: The Macmillan Company.

We lately had occasion in these pages to review a similar book on this subject, and it is interesting to find confirmation by Lieut.-Col. T. B. Quigley of the view that plaster technique is a craft, because, as he states, "it can be acquired by anyone with reasonable intelligence and a modicum of manual dexterity, under competent guidance." The present book is, we think, the best of its type that we have seen; for it does provide that guidance with simplicity and efficiency. It relates for the most part to the use of plaster-of-Paris in the treatment of trauma, particularly under military conditions. It shows how, in the absence of elaborate equipment and plaster tables, it is possible by careful improvisation to obtain perfect results. Even the most experienced workers with plaster-of-Paris using the most up-to-date equipment will probably find much to learn from Lieut.-Col. Quigley's common-sense approach to the matter. The book is well printed, perfectly illustrated, and packed with sensible information.

Notes on Books

Poet Physicians: An Anthology of Medical Poetry written by Physicians, has been compiled by MARY LOU McDONOUGH, and is published at \$5.00 by Charles C. Thomas, of Springfield, Illinois, U.S.A. The task was heavy but congenial, and though a lot of poor stuff is included there are also some lovely short pieces. Mrs. McDonough tried to restrict the scope of the book to "medical poetry," but she has been hard put to it to find any lines by, for example, Keats or Goldsmith which could come within that definition. By contrast, "On a Dead Child," by Robert Bridges, one of the most poignant poems in our language, could probably only have been written by one who had been a children's physician, as Sir Arthur MacNally said lately in his address on "Medical Poets." From the great but scattered mass of verse, bad and good, composed by medical men through the ages, Mrs. McDonough has chosen enough to make an agreeable bedside book. Each of the 110 authors held in her net is introduced with a brief biography, and the volume ends with a memorandum on medical poets by Dr. Merrill Moore, a selected bibliography, and a cumulative index of poet-physicians running to 12 columns of small type. The preface, dated Washington, Nov. 15, 1944, makes grateful acknowledgment to much help from many friends. To anyone who carps at her final choice out of an enormous field the compiler can fairly rejoin (in the words of Dr. Moore) that most medical verse is junk, that she has found this out, and that she has spared the reader 20 poems for every one included; also (in her own words) that she has tried to bring together representative poems from as many languages and from as many eras in the history of medicine as space and exigency make possible.

Dr. LYNN THORNDIKE, of Columbia University, has devoted scholarship of a high order to editing *The Herbal of Rufinus*, and the result is a handsome book published by the University of Chicago Press. Mr. Francis S. Benjamin junior transcribed the Latin text from a photograph of the Rufinus codex of the late thirteenth century and traced most of the citations under the direction of the editor, who supplies a learned introduction and five classified indexes. Although the book of Rufinus remained unknown to modern scholars and to historians of botany and of materia medica until Dr. Thorndike saw the manuscript in 1931 at Florence, it is a work of originality and independent value. Another reason for making his *De Virtutibus Herbarum* available in printed form is that in its quotations from past authorities Rufinus introduces the reader to a hitherto unknown version of Dioscorides. The agents for the book in this country are the Cambridge University Press and the price is 30s.

Dr. R. R. TRAIL's little book *Chest Examination* was written mainly to correlate the anatomy and physiology of the lungs with the physical findings—clinical and radiological. It first appeared in 1943, with a foreword by Sir Walter Langdon-Brown, and now comes to us in a second edition. Illustrative skiagrams have been added, and there are some changes in the order of the text. The illustrations, half-tone or line block, now number 100. J. and A. Churchill are the publishers and the price is now 12s. 6d.

Dr. ALBERT H. ROWE, of San Francisco, whose writings on allergy are well known to workers in that subject, has produced a second edition of his handbook *Elimination Diets and the Patient's Allergies* (Kimpton; 17s. 6d.). So many changes and additions have been made that the text is now entirely reset. Dr. Rowe continues to insist that his trial diets for the identification of possible food allergy should be used as a diagnostic aid, just as blood counts and other laboratory tests are employed in routine clinical pathology, and that detailed menus and special recipes are needed to make possible the total exclusion of all foods eliminated from the diet. He discusses the whole matter in great detail, and in this edition the instructions for elimination diets have been modified to meet wartime shortages of various foodstuffs.

The Garnered Sheaf is a little book of verses by Dr. J. SACKVILLE MARTIN, published at 3s. 6d. by Arthur H. Stockwell Ltd., temporarily housed at Ilfracombe. Many of the short poems are reprinted from the *Poetry Review* or from *Poetry of To-day*. The author has a turn for occasional verse in varying forms, the language is simple, and the mood ranges from tender meditation to playfulness.

The Friends Ambulance Unit has issued from 4, Gordon Square, London, W.C.1, a report of the work done in Europe and the East in September, October, and November, 1945. The F.A.U. comprises 700 men and women who have organized themselves for the relief of suffering wherever it occurs. The first winter of peace is expected to be a period of more widespread misery than any of the wartime winters.

Preparations and Appliances

A CORRECTIVE SPLINT FOR PARALYSIS OF THE THENAR MUSCLES

Mr. J. RUSSELL NAPIER, M.R.C.S., registrar P.N.I. Unit, and chief assistant Orthopaedic Unit, Hill End Hospital (St. Bartholomew's), St. Albans, writes:

This splint is designed to maintain the thumb in a position of function when the thenar muscles are paralysed and at the same time to allow the antagonist muscles to be exercised.

The splint is built round a spong-rubber wedge covered with soft leather that fits into the first interosseous cleft, maintaining the thumb in abduction. The wedge is anchored in position by two leather rings that slip over the index finger and thumb. Attached to the volar-radial aspect of the thumb ring is a strip

FIG 1

FIG 2

of elastic (approximately 2 in. \times 3/4 in. \times 2 cm) which terminates in a third leather ring which fits over the little finger. The leather ring for the index finger should fit loosely enough to allow it to rotate round the finger when the thumb is abducted (Fig. 3).

When the splint is in position the thumb is maintained in the mid-position of rotation (Figs. 1 and 2). The flexibility of the wedge allows a certain degree of palmar abduction and the stretch of the elastic allows a full range of radial abduction (Fig. 3), both these movements being performed against resistance.

Its construction throughout of soft materials eliminates the risk of pressure disturbances on insensitive bearing areas of skin, and permits a complete freedom of all unaffected movements of the wrist and hand.

A criticism that might be levelled against the splint is that it has no fixed anchorage, with the result that the little finger tends to be pulled into flexion and rotation at the metacarpophalangeal joint. Providing that the hypothenar muscles are unaffected, as they would be in a pure median palsy, the disadvantage is very slight and easily outweighed by the advantages of a flexible splint.

I wish to thank Messrs. Beckett and Bird Ltd., of 8, Bentinck Street, London, W.1, for their co-operation.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 5 1946

THE STATE OF THE PUBLIC HEALTH

The health of England and Wales as measured by the statistics given in the Summary Report of the work of the Ministry of Health for the year ending with last March¹ would be a matter for congratulation at any time, but for this country to achieve such a state in the second half of the fifth and the first half of the sixth year of war is indeed remarkable. The year covered by the report extends from a short time before the invasion of Normandy almost to the end of hostilities in Europe—a period during which the war was at its grimmest, public anxiety at its height, and hardships and shortages felt most severely. The E.M.S. hospitals were already filled with the early instalments of nearly 150,000 casualties and sick from the advancing armies in Western Europe when they had to accommodate the victims of flying bombs and rockets in Southern England to the total number of 22,000. The first-aid posts of the London region had to deal with 38,000 air-raid cases in those summer and autumn months of 1944; over 100,000 homeless people passed through the rest centres, and one and a quarter millions migrated from the danger areas. In London itself, on some nights, not far short of half a million were sleeping in public shelters, and as many as 80,000 in tube railways. The presence of some thousands of refugees and the increasing numbers of British repatriates from the liberated territories complicated the problem of the public authorities. These perils to the health of the people had to be combated by a medical and nursing profession greatly diminished in numbers. One-fourth of the general practitioners of the country and one-fifth of the medical officers of the public health services were in the Forces. The local authorities were carrying on with a net shortage of 50,000 people on their staffs as compared with 1939; they were particularly handicapped by lack of professional and technical officers. Yet in such a year not only did the general death rate fall as compared with the year before but the maternal and infant mortality rates, and the mortality rates for the second, third, fourth, and fifth years of life, were the lowest ever recorded. With the exception of dysentery, the incidence of which has been gradually rising for a decade in this country, all the principal infectious diseases showed fewer notifications—notably diphtheria, measles, and pneumonia, which included influenza with pneumonic complications. Even tuberculosis, both in notifications of new cases and in deaths, and venereal diseases, in the numbers dealt with at the clinics, regressed a little, though, of course, both tuberculosis and venereal diseases were well above pre-war level.

¹ Summary Report of the Ministry of Health for the Year ended, March 31, 1945. Cmd. 6710. London: H.M. Stationery Office. (1s. 3d. net.)

To give a few figures: the infant mortality rate in 1944 was 45.7 per thousand live births, and the death rates in the next four years of life were 4.6, 2.6, 2.2, and 1.8 per thousand living; the lowest levels previously were 49.1, 5.8, 3.1, 2.4, and 2.0 respectively. The birth rate was 18.0, but this is based on the mid-1939 population and is subject to modification when the 1944 population is ascertained. The rate has not reached 18.0 since 1925; in the last year of the first European war it was 17.7. The maternal mortality rate was 1.95 per thousand total births, or 1.54 if deaths from abortion are excluded. Of the mothers who had babies during the year 76% had attended the ante-natal clinics, which now number just upon 2,000 in England and Wales, or had received ante-natal care through the welfare authorities' arrangements. Particulars are given in the report of the daily food value of the expectant mother's augmented rations and priority allowances, amounting to 67 g. proteins, 1,450 calories, 1,030 mg. calcium, 5,610 i.u. of vitamin A and 900 of vitamin D, and 39 mg. vitamin C. The vital statistics concerning mothers and infants in the war years are the most encouraging feature of the whole survey:

Year	Maternal Mortality Rate per 1,000 Total Births	Infant Mortality Rate per 1,000 Related Live Births	Stillbirth Rate per 1,000 Total Births	Neonatal Mortality Rate per 1,000 Related Live Births
1939	3.10	50.6	38.1	28.3
1940	2.60	56.8	37.2	29.6
1941	2.76	60.0	34.8	29.0
1942	2.47	59.6	33.2	27.2
1943	2.30	49.1	30.1	25.2
1944	1.95	45.7	27.7	24.5

The figures for 1944 are provisional. The illegitimacy rate is a less pleasing feature. It has gone up from 42 per thousand live births in 1939 to 72 in 1944.

For the third year in succession there was a decrease in both notifications of and deaths from diphtheria. In 1944 both the notifications, which were just upon 30,000, and the deaths, which were fewer than 1,000, were the lowest ever recorded. During the ten years before the war the average annual figures for notifications were twice, and those for deaths more than three times, as high. It is noteworthy that this decline took place at a time when diphtheria of a most severe kind was widespread in Europe. The number of children immunized under local authority arrangements during the year was 561,314. It is estimated that the number of children under 15 in England and Wales at the end of 1944 was 8,714,000, of whom between 60 and 65% had been immunized. The number of deaths from respiratory tuberculosis was 20,104, against 21,342 in 1943. The most serious problem concerning tuberculosis is the present inadequacy of institutional treatment, principally because of shortage of nursing and domestic staff. Up to the end of March, 1945, over 400,000 persons had been examined under the mass miniature radiography schemes, of whom 1 in 100 was suspected of being tuberculous or was definitely found to have tuberculosis. In venereal diseases, more encouraging than the slight improvement in the number of new infections is the number of new patients examined who have been found not infected. The war has delayed the develop-

ment of long-term schemes for the treatment of cancer under the Cancer Act, 1939, but some schemes are now well advanced. A North of England regional scheme based on Newcastle was submitted for the Minister's approval during the year. The Liverpool scheme has extended the area of its operations. Machinery for the preparation of draft schemes was set up during the year in Oxford, Leeds, and Sheffield, and preliminary activities were in progress in the regions centred on Birmingham, Cardiff, and Bristol. The number of deaths from cancer during the year was 72,110, almost exactly the same number as the year before. One person in rather more than seven dies of cancer.

The main statistics given in this report relate only to illnesses which have caused death or which are notifiable. The mass of minor ailments which in the aggregate accounts for the major invalidity of the nation goes unrecorded and any complacency we may feel must be halted by this fact. Until recently the only information about the extent of minor sickness came from approved societies, but since January, 1944, about 2,500 civilians, selected at random, have been interviewed each month through the Wartime Social Survey of the Ministry. A detailed history was taken of all departures from health during the three months preceding the interview. Out of every 1,000 civilians between 16 and 64 only four were reported to have had one or another of the notifiable diseases during 1944, and about six were registered as having died. But in a particular sample of about 5,000 people of those ages it was found that during an average three months period six out of ten had had some illness, not necessarily requiring absence from work, or had complained of a minor ailment of some kind. In the period November, 1944, to February, 1945, out of 100 men and women, 18 men and rather more than 18 women had had colds or influenza, and about four of each sex had been incapacitated. The Minister draws attention in his foreword to one other check to complacency. He points out that it is not at all certain that the improvement in vital statistics will be maintained. Continued vigilance is the condition not only of liberty but of health. Reaction after war strain may be more disastrous to health than war strain itself. Moreover, what Mr. Bevan describes as an "increasingly critical situation" has to be faced in the shortage of nurses, midwives, and domestic workers for hospitals, sanatoria, and maternity homes. The beds he says, are there in plenty (though that does not seem to be the opinion of some at least of the Ministry's surveying officers who have been gathering information about hospital facilities all over the country). It is the personnel which is lacking.

Among other points of interest in the report we note that 8,000 people in areas subject to enemy action, factory workers, and others of all ages in various parts of the country have been examined from a nutritional point of view, and the findings indicated that the state of nutrition was well maintained. The regulation making jaundice notifiable in the Eastern Civil Defence Region continued in force and 3,552 cases were notified—an attack rate of 13 per thousand population. Nine cases of malaria contracted in England were reported during the year—two at a naval establishment in Devonshire, three at Aldershot, and four in the county of Surrey. Periodical inspection

of the static water tanks in the London area (since drained) showed only a small number to be infested with mosquito larvae, the species being *Culex pipiens*, which does no bite human beings. During the year 669,000 gifts of blood were made to the Emergency Blood Transfusion Service. The Service's contribution to the Navy, Army, and Air Force for use over seas amounted to 50,000 bottles of whole blood, 31,000 bottles of dried plasma or serum, and 9,000 2½ litre Winchester bottles of unfiltered plasma and serum. The number of banks of whole blood maintained at hospitals and other blood centres was 441, and in addition there were 33 banks of Rh negative blood.

The report is unusually interesting this year because information can now be given of the measures taken to deal with the results of air raids. The full story of the war refugee scheme since it started operation early in 1940 is also told. One chapter is headed 'Reconstruction', but the reference to the proposals for a National Health Service is only an account of events which occurred in the Willink era. The Minister says that the road to a fitter Britain is now clearly marked. The present major task of his Department is 'a great drive to provide, as quickly as is humanly possible, the good housing on which the health and happiness of the people so largely depend'.

PENICILLIN IN OPHTHALMOLOGY

In diseases of the eye infective processes are largely confined to the outer eye and the various forms of purulent ophthalmia are classical examples, infections of the inner eye, such as panophthalmitis, are on the whole rare. Most inflammations of the eye, of which iritis and choroiditis are characteristic, do not produce pus and the inflammatory exudate does not contain organisms. These distinctions in ocular pathology have been well established for many years, but they gained added significance when the sulphonamides were introduced. It was found that the purulent infections of the outer eye responded readily to general sulphonamide therapy, but, while gratifying results were occasionally obtained in cases of iritis and iridocyclitis the intraocular inflammations generally responded but poorly. Since the sulphonamides easily penetrated the interior of the eye, since adequate concentrations of the drug could be obtained, and since the response in frank infections was better than in serous uveitis it became clear that the whole problem of intraocular inflammation required reassessment in the light of the new and positive knowledge. The sulphonamides have marked limitations. Though some experimental evidence has been advanced that they are effective in infections of the outer eye when used locally, it cannot be said that there is any real clinical support for these observations. It is questionable whether an adequate experimental lesion of the outer eye has yet been evolved, and there is little justification for the wide spread and misguided use of the sulphonamides locally in such infections, while their local use for infections of the interior of the eye has never seemed justifiable in view of their ready penetration through the blood-aqueous barrier. Sulphonamide therapy in eye disease is thus largely oral administration of the drug.

Experience with penicillin in many respects runs counter to that obtained with the sulphonamides. The same fundamental distinction between infection and inflammation has

still to be drawn, but in contrast to the sulphonamides penicillin does not readily penetrate into the interior of the eye when administered intramuscularly. This has been shown experimentally,¹⁻³ and has been confirmed in man.^{4,5} There is no evidence that in the inflamed eye the barrier is less absolute,³ but it appears that the intramuscular administration of penicillin in very many times the dosage currently used might allow some penetration of the drug into the eye.¹ Attempts to obtain more satisfactory penetration by procedures which either delay the excretion of penicillin or modify the blood-aqueous barrier still require fuller study. For the present it must be accepted that the use of penicillin intramuscularly, in contrast to general sulphonamide therapy, has but little scope in infections of the inner eye. A further contrast is in the local action of penicillin. Since penicillin is not inactivated by pus or peptone, as the sulphonamides are, it has proved invaluable as a local medication. This has been brought out in many reports on the use of penicillin locally in acute conjunctivitis, in blepharitis, and in various septic inflammations of the outer eye. The most extensive work on these lines has been recorded in our columns in two papers on ophthalmia neonatorum.^{6,7} However, it cannot be said that the many problems of the local use of penicillin have been solved. Local medication with penicillin requires knowledge of the limits of tolerance and of means for maintaining adequate concentrations. Clinically the limits of local tolerance with the available samples of penicillin have been found to be at about 2,500 units per c.cm. when used in the form of drops. Ointments have not so far been employed widely, as no adequate base has been available. Most of the penicillin ointments were quickly inactivated and became irritants rather than therapeutic agents.⁸ It is possible that this difficulty has now been overcome and more use may be made in the future of penicillin ointments and creams, though limits of tolerance to, and absorption from, such ointments have still to be established. Since penicillin fails to pass the blood-aqueous barrier, it is tempting to inject it directly into the aqueous and vitreous, but it seems that only relatively small quantities can be so injected without damage. The limit of tolerance of the anterior chamber is probably about 200 units, and perhaps rather less for the vitreous.⁹ Experimentally it has been found that massive quantities of penicillin injected into the vitreous produce extensive damage.^{9,10} A less drastic procedure—subconjunctival injection, and though relatively large quantities have been used by some observers¹¹ it appears that the limit of tolerance is again relatively low—injections of about 600 units repeated daily.⁹ With any of these methods concentration and the maintenance of concentration are poor. Drops are soon washed out from the conjunctival sac, and excretion from the anterior chamber of any injected penicillin is rapid. Penicillin

introduced into the vitreous persists for considerably longer, possibly for more than 48 hours,⁵ but injected subconjunctivally it is probably excreted in a matter of hours. The difficulties in obtaining and maintaining adequate concentrations by means of local applications are therefore considerable. These difficulties are illustrated by the studies recorded on ophthalmia neonatorum.^{6,7} Here penicillin in a concentration of 500 units per c.cm. instilled in the form of drops gave less satisfactory results than penicillin in double that concentration, while 1,500 units per c.cm. gave better results still, and with a concentration of 2,500 units per c.cm. recovery became the rule. Instillations at intervals of half an hour gave better results than hourly instillations, while remarkably rapid clearing of the infection took place when penicillin was instilled at intervals of five minutes. Even better results may be expected when penicillin is administered almost continuously—that is, at intervals of one minute for half an hour.¹²

It is generally accepted that penicillin, like the sulphonamides, is ineffective against virus diseases. There is, however, ample evidence that the sulphonamides are effective against some of the larger viruses, such as those of lymphogranuloma inguinale and rat pneumonitis. They have also proved invaluable in trachoma and in inclusion blennorrhoea. Successes with local penicillin in inclusion blennorrhoea^{5,7} suggest that it may also prove of value in trachoma—and presumably in other infections due to the larger viruses; and, indeed, promising results are already on record.^{9,13,14} In contrast to the uncertainty as to the action of penicillin on viruses is its established efficacy against the spirochaete. The possibilities thus opened in the treatment of ocular syphilis have as yet scarcely been explored.^{9,15} For the present the scope of penicillin in ophthalmology seems confined to its local use in external infections of the eye. Little is to be hoped for from general administration, while the introduction of penicillin directly into the eye still presents many difficulties that require intensive study. But if methods for the direct introduction of penicillin into the eye are evolved, then in many conditions treatment by the oral administration of sulphonamides may well be replaced by the local application of penicillin.

HEALTH OF FACTORY WORKERS IN 1944

In the report of the Chief Inspector of Factories for 1944¹⁶ Dr. E. R. A. Merewether, the senior medical inspector, is responsible for a very full and detailed article on "Industrial Health." It forms, in fact, nearly a third of the whole report, and Dr. Merewether points out that an increase in the importance of industrial health is evident in many ways. Several universities are establishing departments of industrial health, fellowships are being provided for those who wish to qualify for teaching and research posts, and the Medical Research Council has set up research units at several centres. Most industries can be improved so far as health and safety are concerned, and Dr. Merewether maintains that it is essential for industrial research and industrial health research to be closely integrated on a national scale.

¹⁶ Annual Report of Chief Inspector of Factories for 1944. Cmd. 6698. H.M. Stationery Office. (1s. 6d.)

The statistical tables given in the report show that in 1944 lead-poisoning cases reached the lowest annual figure on record, and for the first year since official figures have been kept no case of poisoning in the pottery industry was notified. What a contrast with the experience of 1900, when no fewer than 210 cases were recorded! Perhaps the chief protecting factor is the almost universal adoption of leadless or low-solubility glazes. The poisonous effects of TNT were distinctly less marked than in 1943, there being 36 cases of "anilism"—i.e., haemolytic action on the red blood cells evidenced by cyanosis and shortness of breath—11 cases (1 fatal) of toxic jaundice, and 6 cases (5 fatal) of toxic anaemia. The cases of epitheliomatous ulceration of the skin numbered 205 (20 fatal), and showed a substantial rise on 1943, when they were 160 (15 fatal). Of the 45 cases due to mineral oil, cotton mule spinning contributed 38 (13 fatal), and it is much to be regretted that the effective modern methods of treatment in the early lesions of the skin from agents known to be carcinogenic were not always employed. The cases of gassing numbered 450 (25 fatal), and were only about two-thirds as numerous as in the immediately preceding years, those due to nitrous fumes being only about a fourth as numerous.

The subject of pneumoconiosis is discussed at some length, and Dr. Merewether points out that it is only by studying the cases statistically over many years in relation to the causative industries and processes, and to economic factors such as housing and nutrition, that it will be possible to assess the relative risks and the progress achieved in reducing them. One table sets out particulars relating to 1,750 fatal cases of silicosis, with or without tuberculosis, and 190 fatal cases of asbestosis, which have been investigated by the Factory Department since 1929. The average duration of employment in the cases of silicosis was 34.0 years, and in cases of asbestosis 15.1 years, the averages when these diseases were complicated by tuberculosis being 31.3 and 10.4 years respectively. In some cases it has been possible to replace siliceous by non-siliceous materials—e.g., in grinding wheels for metals, and by substituting alumina for flint in placing china. In other processes measures have been adopted to reduce dust, and these and other factors have resulted in a distinct lowering of mortality. A comparison of 1935–8 with 1941–4 shows that the yearly mortality in the pottery industry fell from 52 to 41, and that in sandstone industries from 95 to 67. However, deaths from fibrosis of the lung observed in coal mining have gradually increased.

The report gives a detailed account of the latest observations on the effects of radio active substances. The number of luminizers employed has risen steadily from year to year, and in 1944 they amounted to 561. The National Physical Laboratory examined them by a dental film test, and found that almost all were exposed to less than 10 roentgen per week. In half a dozen firms, however, groups of workers were exposed to much heavier dosages in some cases exceeding 50 roentgens per week, and the causation of the excesses is discussed. The health of 450 of the luminizers was investigated by Dr. Ethel Browning and was found to be remarkably good. The incidence of slight dermatitis of the skin of the fingers around the nail was considerably less than usual, owing chiefly to the use of a protective paint container, and the requirements of a Factories Order prescribing for all luminizers an interval of three months' removal from contact after one year's continuous employment. Disturbances of the blood picture were slight in character, and showed no tendency towards aplastic anaemia.

Medical and nursing services in industry continued to develop in efficiency. At the end of 1944 there were 180

doctors exercising full-time medical supervision in 275 factories, and 890 exercising part-time supervision in 1,320 factories. There were about 7,600 women nurses and 200 male nurses. The Docks Medical Services continued to develop and were highly successful. For instance, at Liverpool 9,034 new cases were dealt with, two-thirds of them relating to dockers. In summarizing his report Dr. Merewether emphasizes the immensity of the scene portrayed, and the widespread interest in industrial health evinced by all sections of the community.

THE METRIC SYSTEM

In a letter from Istanbul Prof. W. C. W. Nixon¹ made in our columns a plea for the adoption of the metric system in medicine. Other correspondents supported him, and if there were any whole-hearted advocates of the imperial and apothecaries' units they remained silent. The metric system is used universally in scientific work, and for all purposes in many countries, and it has the merit of practical simplicity. There are other good reasons for adopting this system in medicine. Sulphonamides are already prescribed and dispensed metrically, and so are numerous other drugs which have helped to alter prescribing habits. Doctors who have been abroad during the war and have had to use the metric system in prescribing seem to have done so without much difficulty.

An abrupt change to the exclusive use of the metric system would lead to confusion, but it seems that the time is ripe for the introduction of the metric system throughout the *Journal*. One of the principal reasons for doing this now is to enable the medical man abroad to read the *Journal* in terms of the system of weights and measures familiar to him. More than 15,000 copies of the *Journal* are sent abroad each week, and the foreign doctor is looking eagerly to this country for professional and technical information. We hope, too, that increasing familiarity with the metric system will encourage British doctors to hasten the end of a system which isolates us from the rest of the scientific world. Metric equivalents will be inserted parenthetically after each old style dose, weight, and measure from this issue onwards. This is the beginning of a phase of transition which we optimistically hope will end in the general use of the metric system in British medicine. How long this phase will last remains to be seen, but in the United States the same transition phase has recently ended.² It began in 1900 which is a sobering thought.

The War Office has announced releases of doctors from the R.A.M.C. for January and February as follows:—General duty medical officers: Groups 25–30 in January; Groups 31–38 in February. Specialist medical officers: Groups 25 and 26 in January; Group 27 in February. The greater age of entry of specialists has the effect of bunching the majority of specialists into the first thirty groups. The release of specialists in Groups 1–27 is proportionately equivalent to Groups 1–38 in the case of general duty medical officers. The Central Medical War Committee is taking steps with a view to securing the recruitment of further specialists to enable releases to proceed at a proportionate rate with general duty medical officers.

The first part of the New Year Honours List is published while this number of the *Journal* goes finally to press, and we must therefore wait a week to announce the medical names, of which there are many.

OCULAR SIGNS IN THE PRISONER OF WAR RETURNED FROM THE FAR EAST

BY

G. C. DANSEY-BROWNING, D.O.M.S.

Major, R.A.M.C.

AND

W. M.-RICH, D.O.M.S.

Capt., R.A.M.C.

Large numbers of men released from Japanese prison camps will soon be arriving in this country. At a military ophthalmic centre we have during the past two months examined some 30 men who were released at the recapture of Rangoon. They had all been prisoners of war for from two to three years. During this period they had been compelled to do hard manual work on a wholly inadequate diet, the bulk of which was rice. They had no headgear and little or no protection against the sun. Those who wore glasses had these removed when captured, and they were never replaced. The majority had suffered from dysentery (26 cases), malaria (15 cases), and beriberi (27 cases). The following ophthalmic case records of these men are submitted as a basis for discussion.

Report on Cases of Beriberi

Two of the men had suffered from "wet" beriberi, and three others had had both "wet" and "dry" forms of the disease. The other 22 had "dry" beriberi. The average duration of the disease was six months, and most of the men had noted that their sight was failing towards the end of their illness.

Ocular Signs.—On examination 10 cases were found to have bilateral central scotomata. In not one of these 10 was there contraction of the peripheral visual field either to white or to colours. There was no constancy in their colour scotomata. Five of the 10 had a degree of visual failure which prevented their corrected vision being brought above 6/60. The ophthalmoscopic examination of these 10 cases revealed that all 20 optic disks showed some degree of pallor. In the eight cases presently to be described four of the optic disks showed an apparent primary optic atrophy; four showed pallor of the papillo-macular bundle; in the remaining eight optic disks there was pallor of the temporal half. The four cases of apparent atrophy had pupils that were relatively enlarged, but these pupils retained their normal reactions to accommodation.

Among the 20 cases without scotomata, one man alone showed some difficulty in convergence; he had a long-standing defect in one eye—"amblyopia ex anopsia." The cases with scotomata did not reveal evidence of ocular muscle paresis. Another of those without scotomata achieved bilateral vision of 6/9 on correction. He stated that at the time of his "dry" beriberi he had suffered from a considerable amount of photophobia. He was treated with a "kind of bran," and indeed was the only man to receive anything but the most crude type of medication in captivity. His ocular symptoms had disappeared with the cure of the beriberi.

Earlier this year we examined two men who showed leucocoma but no optic nerve degeneration as a cause for visual failure. They had been for a long period prisoners of war of the Japanese, and had been rescued by a submarine that had torpedoed their prison ship. They attributed their eye condition to the long period of immersion in the oily sea.

It is of some interest that not one of the 30 men examined in this series showed ocular signs of ariboflavinosis. Yet during the same period we have seen two men back from German prison camps who, though they did not have beriberi, had a definite increase of limbal vascularization. The accompanying table summarizes the detailed investigation of eight of the ten cases of bilateral central scotomata.

Discussion on the Cases

General.—Elliott (1920) states that beriberi is mainly a disease of the young adult of between 16 and 30 years of age. In Japan the disease is apparently most common in the hot weather from July to September; while the ocular manifestations are most often seen in November, December, and January. Out of 6,000 patients examined by Ishihara, 32 showed amblyopia; 6 of the cases of amblyopia were due to beriberi. Elliott does not, however, say how many of the cases had bilateral amblyopia. Maynard of Calcutta associated glaucoma but not optic atrophy with "wet" beriberi. We have no evidence to offer in connexion with this point.

Retrobulbar Neuritis.—In 1895 Kono stated that the characteristic ocular signs of beriberi were: (a) central scotoma, (b) amblyopia, (c) contraction of the visual field. Elliott adds that as the scotoma increases the central vision rapidly falls to 6/60, but thereafter remains relatively constant. There has been considerable disagreement as to the constriction of the peripheral visual field. Coppez definitely states that there is no contraction. Ishihara says that it occurs, but only transiently. Yamaguchi claims that there is only constriction in the red and green peripheral fields.

Fundus Appearance.—Yamamoto states that there may be: (a) no apparent fundus lesion; (b) partial optic atrophy, limited to the temporal quadrant; (c) the whole optic-nerve head may show atrophy. Ishihara states that the papillo-macular bundle is most often affected.

Scotomata.—The resemblance of the scotomata of beriberi to those due to tobacco-alcohol, lead, quinine derivatives, and general cachexia was early recognized. Miyashita described the scotoma as "pestle-shaped," and said that it connected the blind and fixation spots. Aoki and Yamamoto stated that the colour scotomata lay within the white scotoma, in the following order of diminution: green, red, and blue. Over this point there has been much dispute. Miyashita says that the colour sense is often disturbed, especially for green. In our series there was a "tail" to the white scotoma leading from the fixation spot towards an enlarged blind spot. There did not appear to

Table giving Details of Eight Cases of Bilateral Central Scotomata

Patient	Age	Unaided Vision	Aided Vision	Date of Capture	Length of Captivity	Beriberi			Malaria	Dysentery	When Sight Failed	How Affected	Remarks
						Type	Duration	Onset					
A	27	Rt. 6/18 Lt. 6/18	6/18+ 6/18+	12/3/42	3 years	Dry	7-8 months	March, 1943	Yes	Yes	April, 1943	Centre of objects blurred.	Scotoma of rt. eye absorbs blind spot
B	31	R. <6/60 L. <6/60	<6/60 <6/60	24/2/42	3 years	Dry	7 weeks	April, 1943	4 attacks	No	April, 1943	Vision decreased before paresis appeared	—
C	26	R. 6/18 L. 6/60	6/9 6/36	12/3/42	3 years	Dry	—	Jan., 1943	2 attacks	Yes	Nov., 1943	Not recognize people 30 yds. and near sight	"Tailed scotoma"
D	23	R. 6/36 L. 6/36	6/24 6/18	29/3/43	2 years	Dry	6-9 months	Jan., 1944	Several attacks	Yes	Early 1944	Rapid onset: people's faces blurred, rest clear	"Tailed scotoma"

be any "nuclei" lying between the blind and fixation spots. Our colour scotomata were inconstant.

Paresis of Ocular Muscles—Manson states that such pareses are rare. Yamaguchi found all types of paresis and, above all, that of accommodation. Stitt merely states that there is no Argyll Robertson pupil. Da Silva Lima in his Brazilian case noted paresis of the sixth cranial nerve. Elliott found ptosis, and noted that most Japanese authorities agreed that there was some paresis of the sixth cranial nerve. We found no paresis in the 10 cases with scotomata.

Diminution of Sensitivity of the Cornea and Conjunctiva—In 1918 Ishizu referred to such diminished sensitivity. In 1899 Tzurumaru associated retrobulbar neuritis with xerosis and xanthopsia. In 1930 Ozuchi reported cases of superficial keratitis with a coincident retrobulbar neuritis in which there was a deficiency of vitamin A. We found no diminution of sensitivity in our series; neither was there evidence of xerosis. Photophobia had been noted by one man but no xanthopsia or hemeralopia.

"Dry" Beriberi: Pathology; Prognosis; Treatment

The pathological findings in the central nervous system are demyelination, haemorrhages and subacute inflammation of the white nerve-fibres and the surrounding membranes. Some axis-cylinders are found to be fragmented. In regard to the muscle pareses, Wright noted "a mild chromatolysis in the trophic cells of the affected nerve-fibres" (Nissl). Kagoshima, on post-mortem section of five cases that had shown scotomata, found a "distinct and limited atrophy of the fibres in the outer section of the optic nerve in all of them."

Miyashita holds that the poorly nourished individual is the most likely to develop eye symptoms. But even in the worst cases the central vision rarely falls below 6/60. Elliott only states that complete blindness need never be anticipated. The men of our own series of cases had been told that their sight might recover in the next eighteen months. We have been unable to find an authority for this prognosis. Even allowing for slight improvement due to diminution of inflammation, surely the damage to the optic nerve itself is irreversible. Also the prognosis in cases of bilateral retrobulbar neuritis from other causes is always gloomy.

Elliott states that in Japan it is usual to stop the intake of rice and to substitute a bean called "azuki" (*Phaseolus radiatus*). Aoki states that under this regime the scotomata rapidly diminish, only to return when the ingestion of rice is resumed. Yamamoto combined barley with the bean diet, and Yamaguchi claimed a total recovery of all eye symptoms in one case after a month's dieting. Elliott claims that "if this rational line of treatment is not adopted the prognosis is a bad one."

Vitamin Deficiency

All the early authors apparently associated beriberi with the removal of the pericarp of the rice in the process of "polishing." This removal of vitamins B₁ and B₂ has now come to be regarded as the main cause of the nerve signs. Lindsay Rea (1938) quotes Fitzgerald Moore (Nigeria, 1934) as noting that a deficiency of both vitamins A and B produced an optic neuritis. He states also that in the Philippines a lack of vitamin B was responsible for keratitis. Deficiency of vitamin A may lower the standard of resistance to infection, but it is not responsible for neurological signs (Woolbach). Hemeralopia, was not one of the symptoms that our patients complained of, neither had they signs of xerosis. Kemoto reports one case with hemeralopia and scotoma of 18 years' duration. Vedder, in 1940, stated that diets deficient in vitamins A and B cause nerve degeneration, and postulated an "X" cause for "dry" and "Y" for "wet" beriberi. But pellagra patients (B₃ deficiency) seldom show optic atrophy.

The modern theory of the causation of tobacco-alcohol amblyopia holds that defective intestinal absorption is responsible for a deficiency of vitamin B, and that this deficiency is responsible for the consequent optic atrophy. Vitamin B is not stored in the body, and the daily requirements of the adult are from 300 to 750 i.u. In hot climates there is increased consumption of B₁, especially when the subject is engaged in hard manual work. The intestinal upset of dysentery will prevent the absorption of B₁, and a starchy diet will make a

B deficiency manifest itself earlier. Rice that has gone mouldy loses most of its vitamin content. But increased vitamin B₁ in the diet will not restore visual function in either beriberi or tobacco-alcohol amblyopia, although the peripheral nerve symptoms of beriberi are ameliorated.

We feel, with Meiklejohn (Stitt, 1942b), "that the exact nature of the deficiency of nutritional neuritis remains obscure," but we do regard the damage done in beriberi to the optic nerve (a true portion of the C.N.S.) as final.

Conclusions

We trust that we have shown a relationship between the scotomata to white in our series of cases and those of the toxic amblyopias. The question of the shape of the colour scotomata can be settled only after examination of several hundred cases.

Deficiencies of vitamins B₁, B₂, and (very dubiously) A appear to have played their part in the ocular signs of beriberi.

We submit that bilateral optic nerve degeneration in beriberi is more common than the literature would indicate.

We think that the ocular signs of the disease do not of necessity include a contraction of the visual peripheral field, also that ocular pareses is uncommon.

We conclude that, as the optic nerve is part and parcel of the C.N.S., the damage done to the nerve proper by the acute optic neuritis of beriberi is final, and that any improvement of vision can be but slight.

Summary

Ocular signs in 30 recently rescued prisoners of war have been described.

Eight cases are discussed out of ten who showed evidence of: (a) bilateral retrobulbar neuritis; (b) no constriction of the peripheral visual field; (c) no ocular muscle paresis; (d) scotomata to a white target with a "tail" from the fixation point leading to the enlarged blind spot.

The relevant literature has been discussed. (Our main source of reference has been *Tropical Ophthalmology* (R. H. Elliott, Oxford Univ. Press 1920). This contains many references to Japanese authorities.)

We would be extremely grateful for any information on beriberi cases with similar ocular signs from the wealth of clinical material that will shortly be available.

PARACENTESIS AND MYRINGOTOMY: A QUESTION OF TERMINOLOGY

BY

T. B. JOBSON, M.D., B.Ch.

There are two minor operations on the ear which are quite distinct in technique but confused in nomenclature. One is the withdrawal of fluid from the middle ear by means of a hypodermic syringe and a 2-in. (5-cm.) hypodermic needle bent at an obtuse angle. This operation is not mentioned in any of the books on otology that I have seen. It is a valuable diagnostic procedure. In many cases I have been able to establish the fact that fluid was present and to identify the causal organism—always a single organism, whereas the pus from a discharging ear often yields several organisms. This drawing-off of fluid by a syringe from other parts of the body—for example, from an empyema—is termed paracentesis. Unfortunately, the term paracentesis is used in a large number of the books on otology to imply making an incision in the tympanic membrane for the purpose of drainage.

The derivation of these terms, myringotomy and paracentesis, is interesting and should help us to make a choice.

Myringotomy is a comparatively modern word. It was first used by Gruber¹ in 1863 and appears later in Ravogli's "La Miringotomia."² Mr. Rome, our helpful librarian at the Royal Society of Medicine, has kindly found these references for me. The actual articles are not in the library and can be found in this country only in the library of the Royal College of Surgeons, which is at present dispersed. The term myringotomy, although a hybrid, expresses accurately the operation of incising the tympanic membrane. It is derived from *myringa*, the membrane, a modern Latin word, and *τεμνω*, I cut, a Greek word.

MYRINGOTOMY

FIG. 1

When we come to paracentesis we are on more debatable ground. Paracentesis is a very old word, and was used by Galen, not as applied to the middle ear but in the sense of tapping for fluid in cysts, ascites, etc. It is interesting to read Galen's exact words on this subject. A friend (Mr. Burns) has kindly translated this extract for me.

"Tumours usually occur in the wrists and we remove them for the most part from women who are workers in wool; these also can be mollified by wax salve. Tumours and abscesses in the armpits we remove by cutting round them; similarly when they are found in the groin. In dealing with abscesses between the ribs, we make a distinction, and do not draw off all the matter altogether but little by little. . . . Sufferers from dropsy we tap slightly with an iron instrument shaped like a myrtle leaf, passing in from the left until it reaches the cavity."

FIG. 2.—A leaf of *Myrtus communis*.

Παρακέντησις means "poking through or across" and exactly expresses what Galen did. This is also what is done in drawing off fluid from the middle ear by means of a bent hypodermic needle attached to a syringe.

PARACENTESIS

FIG. 3

suggest that this operation should be known as paracentesis. rue, it has not quite the Galenical meaning, but we need a word to denote the suction of fluid from the middle ear. It is incorrect to use this word to mean cutting the membrane.

¹ Gruber, I., "Die Myringotomie als Heilmittel gegen Schwerhörigkeit und Ohrensausen," *Allg. Wien. Ztg.*, 1863, 8, 305, 313, 321, 329, 338.
² Ravogli, A., "La Miringotomia," *Arch. di Med., Chir. ed. ig Roma*, 1875, 7, 321.

A David Anderson-Berry silver-gilt medal, together with a sum of money amounting to about £100, will be awarded in 1947 by the Royal Society of Edinburgh to the person who, in the opinion of the council, has recently produced the best work on the therapeutic effect of x rays on human diseases. Applications for this prize are invited. They may be based on both published and unpublished work and should be accompanied by copies of relevant papers. Applications must be in the hands of the general secretary, Royal Society of Edinburgh, 22, George Street, Edinburgh 2, by Dec. 1, 1946.

DESIGN AND CRAFTSMANSHIP FOR THE TUBERCULOUS

A new attitude is coming over rehabilitation of tuberculous patients. No longer need one think exclusively of chicken farms, garden seats, leather bags, and the routine of factory life. The tuberculous subject has very often high mental endowment, and the field of art and creative design is one in which he can obtain constructive openings. The matter was discussed at a conference called by the National Association for the Prevention of Tuberculosis, and very largely attended by representatives of the medical profession, occupational therapists, and artists. It appears that there are at least 83 industries in this country where draughtsmen, craftsmen, designers, and workers in decorative and applied art are employed.

Commerce and Therapy

The DUCHESS OF PORTLAND, who took the chair, said that congenial employment was for tuberculous patients the breath of life. There was no reason why such patients should not produce first-class work of commercial value, and not merely something which depended for its sale on the charitable appeal of the sad label "Work by the Disabled." Sir WILLIAM CRAWFORD stressed the quality of British goods, but said they were not presented attractively enough and lacked colour, form, and design. Here was a field for the tuberculous patient—a field offering continual new interest which was beneficial to the patient, and one in which the work was both light and remunerative. Mr. PHILIP JAMES, director of the Council of Arts, said that people did not yet fully understand the healing powers of art. From the practical point of view there were two essentials: that instructors should be experts who encouraged creative design, not slavish copying, and that goods produced should be of commercial value and not "just Christmas presents." Mr. H. W. YOXALL emphasized the importance of good design, both for selling goods and for its therapeutic effect. The work taught should be work which would sell on its own merits and not on charitable appeal, and he advised concentration on industrial design for which there was an assured market, rather than on arts and crafts which called for specialized selling.

Dr. W. C. FOWLER, medical superintendent of Pinewood Sanatorium, thought from his own experience that about 10% of patients had clear potentialities, but that every tuberculous patient would benefit from the raising of the general standard of culture. He touched on the question of infection, and said that all articles made were easily and quickly disinfected. Many other points were raised in discussion. Dr. R. R. TRAIL, medical director of Papworth Village Settlement, pressed for two practical measures: the appointment of artists to teach people on an agreed scheme, and the obtaining of definite offers from commercial firms to consider the designs and work produced. These conclusions embodied the opinion of the meeting.

These general ideas have now to be translated into action, and the N.A.P.T. intends to make a practical scheme through which any tuberculous patient who needs help and coaching in exploiting his talent to the full in arts and crafts will not fail to get it.

MEDICAL LIBRARIES OF EUROPE GIFT FOR A CENTRAL BUREAU

The Rockefeller Foundation has made an appropriation to the Royal Society of Medicine of a sum not exceeding £61,725, for capital expenditure and tapering maintenance over four years, to establish a Central Medical Library Bureau. The immediate function of this organization is to help in the rehabilitation of medical libraries on the Continent which have suffered through deprivation or devastation, and its long-term function the exchange of scientific medical information between individuals and institutions.

The method to be employed initially is the use of microfilm. A number of the best "microfilm readers" obtainable will be bought by the Society and lent to participating institutions. The scheme approved by the Rockefeller Foundation contemplates that while the work of rehabilitation is being carried on, interchange of information between medical libraries will be developed into a permanently functioning scheme which can continue to operate when rehabilitation is completed. Thus the more permanent function of the Central Medical Library will

be gradually established and the subscriptions of individuals and of associated libraries should enable the Royal Society of Medicine to continue the service without further help from the Rockefeller Foundation.

Preliminary work on detail of this scheme is in active progress. A conference will be convened by the Society at an early date to which institutions concerned in its original scheme will be invited to send representatives in order that the new plan may be laid before them.

LONDON VOLUNTARY HOSPITALS

INCREASING PUBLIC SUPPORT

King Edward's Hospital Fund for London has performed another service by producing an elaborate analysis of the finance and work of 167 voluntary hospitals in London in 1944.¹ The financial tables show the impressive volume of public support which these hospitals continued to command even in the year when London was subject to flying bombs and other war distractions and when in consequence the hospitals themselves had fewer beds occupied and fewer people coming to the out-patient departments. The subscriptions and donations rose by £80,000 over the amount for the previous year and reached a figure of £1,144,000. Contributory schemes brought in a further £733,000, again a considerable increase, but patients' payments were, of course, down.

The amount derived by the voluntary hospitals from the public authorities worked out at just over 30% of their total maintenance income. This amount differs widely as between different classes of hospitals and as between different hospitals in the same class. For the twelve teaching hospitals the total sum received from public authorities was £725,429, being 32.9% of income, and in the larger general hospitals without medical schools the percentage was higher, and in some of the special hospitals—the chest hospitals, for example—it rose to more than half the income. The total sum received by all the hospitals from public sources was £1,803,000, an increase of £373,000 on the year, the increase being due to grants under the E.M.S. scheme and towards the increase in nurses' salaries. The public is generous to the voluntary hospitals, but, on at any rate a superficial reading of these figures, erratic in its preferences. The teaching hospitals receive only 15% of their income from subscriptions and donations, but the larger non-teaching hospitals receive a considerably larger proportion—possibly a reflection of local pride. Of the teaching hospitals the favoured one in 1944 was the Royal Free, which received 45% of its income in the form of voluntary gifts, whereas St. Bartholomew's received only 11%; but St. Bartholomew's has a far larger income from invested property than any other hospital.

The total bed complement of these 167 hospitals at the end of 1944 was 23,377, but the number of beds open to patients was 17,721, and the average number occupied daily during the year was 10,405. One perplexing feature at first sight is the great difference between the average periods of residence of patients in different hospitals, even hospitals of the same class. In the teaching hospitals the average period varies from 21.4 days at the London to 12.9 days at St. Bartholomew's. It is a little difficult to see why the average period of residence should be twice as long at the Metropolitan Hospital as at St. John's, Lewisham, or twice as long at Hendon as at Purley. Among the children's hospitals the average stay of patients at Queen Elizabeth's is 21 days and at Paddington Green 11 days. No doubt the position is influenced by the number of patients who stay, particularly at certain hospitals, for very short periods. For example, at St. Bartholomew's 1,488 patients were in the wards for three days or less, as compared with 564 at Middlesex and 587 at Westminster, each of the hospitals having about the same total number of in-patients. Other factors may be the ratio of medical to surgical beds in different hospitals and the existence of convalescent-home facilities.

CARE OF CHILDREN UNDER FIVE

Recognizing as an "unattainable ideal for the present" a situation in which mothers of children under 2 years of age will be discouraged from going out to work, the Ministers of Health and of Education have in a recent circular, asked local authorities to make plans for adapting wartime nursing services to present needs and to submit these plans by the end of February. It is pointed out that for some time to come the need for women workers in certain vital industries may be as urgent as it was in wartime, and thus, with housing and shopping difficulties, makes it necessary that provision for the day-time care of children up to the age of 5 should continue, including some for the "under 2's," who are not admitted to nursery schools and classes. The methods to be adopted will rest with the local authorities, but the circular suggests a combination of the following: nursery schools, nursery classes, day nurseries, and schemes of day guardians, using maternity and child welfare centres on two or three afternoons a week as temporary crèches; organizing responsible women or older girls as volunteers to "sit in" at the homes of children while the parents go out together in the evening. Local authorities are asked to consider which wartime nurseries should continue to be run under maternity and child welfare powers; which should be taken over and run as nursery schools or nursery classes; and which should be closed. The cost of running wartime nurseries and wartime nursery classes will continue to be borne by the Exchequer until March 31. From that date such wartime nurseries as become nursery schools or nursery classes will attract the normal education grant from the Ministry of Education. Wartime nurseries continuing as day nurseries will receive a similar grant from the Ministry of Health. This grant will also be payable for registered day guardian schemes, afternoon crèches, and evening "sitters in."

MEDICAL FOUNDATION OF EPSOM COLLEGE

In spite of a long list of pensions, annuities, and scholarship, totalling over £13,000, awarded during 1945 the Royal Medical Foundation of Epsom College has to announce that owing to lack of funds many deserving applicants—medical men and women, and children of school age—remain unassisted. There is a waiting list of 28 applicants for pensions and 24 for annuities. The object of this Foundation is to help the families of less fortunate colleagues, and that this aid is given far and wide is seen from the following list for 1945:

General pensions	£
41 Foundation scholarships for boys educated, clothed, and maintained entirely free of cost	1,593
13 school trips for girls	676
15 exhibitions for boys	570
133 pensions and annuities of varying amounts	615
Grants towards education of 38 boys and girls	2,935
Grants to widows and spinsters	949
	322

When it is realized, however, that to maintain this assistance the Foundation has to rely upon the generosity of subscribers for over £10,000 a year, then the need for more and larger subscriptions is only too apparent. An appeal is therefore made for all who can to help the Foundation in its work in 1946. Subscribers may, if they wish, ask for their contribution to go to some particular beneficiary, and here it may be mentioned that the Sherman Bigg Fund enables the Foundation to make educational grants for those who cannot obtain scholarships. Subscriptions and donations for whatever aspect of the work may be sent to the Secretary, Epsom College Surrey.

A POLICE EXHIBITION IN 1946

A Police Exhibition is to be held at Brighton from June 4 to 22, when the Chief Constables (Cities and Boroughs of England and Wales) Association will hold its fifteenth conference. The Brighton Corporation is lending part of the Municipal Art Galleries and Museum for the exhibition. Its objects will be to create a wider public interest in the preventive and detective aspects of crime, and to draw attention to the advances made in forensic science. Certain scientific and criminal exhibits will be shown privately in the Royal Pavilion. Invitations will be extended to members of the legal, medical, and scientific professions, magistrates, and police to visit this.

The Home Secretary has shown his interest in the exhibition, and the Home Office is helping in the preparatory work. The Commissioner of Police of the Metropolis is lending exhibits from the Museum at New Scotland Yard, and chief constables and directors of Home Office Forensic Science Laboratories are contributing from their collections. Offers to lend documents, records, and exhibits of historical, legal, criminal, or scientific interest will be welcomed, and correspondence should be addressed to the Chief Constable of

Reports of Societies

DIET IN MENTAL ILLNESS

In the Section of Psychiatry of the Royal Society of Medicine on Dec. 11, with Dr. G. W. B. JAMES in the chair, there was a discussion on the importance of diet in mental illness.

Dr. W. REES THOMAS said that the point which had impressed him during his years in mental work had been the necessity for a varied diet. The history of dietetics in mental hospitals made sad reading. Twenty or thirty years ago little was known about diet, and the patients, though reasonably well fed, suffered from various dietetic deficiencies which he hoped did not exist to-day. In 1942 he undertook a special examination of a large number of patients in mental hospitals to discover whether there was evidence of vitamin deficiency; there was very little evidence of deficiency of vitamin C, and vitamin A was not shown to be deficient at all. The death rate in mental hospitals during the war was very much lower than during the war of 1914-18, when the increase of deaths in the mental hospital population became alarming; yet during the war just ended overcrowding had been greater, ventilation (owing to the black-out) had been poor, and shortage of nursing staff acute. From 1939 to 1941 the death rate rose gradually, but it began to fall in 1942, and by 1944 was at about the pre-war figure. In his view the difference in the position in the two wars was due to the recognition of the importance of diet. From a diet analysis carried out in 1942 it appeared that in two-thirds of the mental hospitals of this country the mean calorie value of the ordinary diet was 2,360 calories a day. Some 27% of the patients, owing to the circumstances of their work, received extra food, and 10% had extra food for other reasons. Such a calorie value was fairly good when it was remembered to what a large extent the population consisted of old people. The common complaint was lack of variety.

Mental Hospital Diet and the Rationing System

Dr. H. E. MAGEE said that the Special Diets Committee of the Medical Research Council, which advised whether patients suffering from any particular disease should have special allowances of rationed or other foods, had not recommended any priorities for mental patients, though such patients suffering from other complaints—e.g., diabetes or tuberculosis—were entitled to the prescribed allowances, and mental hospitals, like other institutions, could obtain a priority allowance of 2 lb. fish weekly for every patient requiring a light diet. The individual patient varied in his requirements according to the amount of muscular exercise he performed, from 3,500 calories a day for those who worked in the open air to 2,400 for those who did quiet and confined work indoors. Other things being equal, the needs of mental patients varied with their complaints. The melancholic or paranoic type might require only 2,000 calories a day, whereas the excitable type, with exaggerated reflexes, lack of co-ordination, continual unrest, and insomnia, might require 4,000 or more. Probably the need of the average adult male patient in a mental hospital was about 3,000 calories, and of the female 2,200. Could this be given under present rationing system? If the diet included all the needed and "points" foods, and if bread, potatoes, oatmeal, fresh vegetables were given to satisfaction, there need be no fear of deficiency, whether in regard to energy value, proteins, minerals, or vitamins. In a diet of 3,000 calories, if a sensible choice were made of the "points," rationed foods would supply about 1,040 calories and 35 g. protein, mostly of animal origin. The remaining 2,000 calories would come from bread and flour (1,100), potatoes and oatmeal (220 each) and from such accessories as sausages, fish, and offal. These unrationed foods provided about twice as much protein as the rationed foods; it was true that it was mostly vegetable protein, but the evidence showed that enough proteins for the body's needs could be obtained from purely vegetable foods. It could not be said that the human body required animal protein as an indispensable part of diet after the stage of childhood had passed.

It was sometimes complained that people were not getting enough protein and that their diets were too starchy. But

Dr. Magee argued that as a general rule it could be taken that if a person of ordinary tastes consumed sufficient calories from the food available he could scarcely avoid having enough protein, minerals, and vitamins. In fact the wartime food policy had been so planned as to make this possible. In conclusion Dr. Magee placed before the meeting the results of some observations made in 1942-3 in the male mental hospital of St. Anne in Paris by Randoin. Before the war the average calorie intake was about 2,877 daily, and the death rate 10%; in 1941-2 the average calorie intake was about 1,750 and the death rate 21%. On this level of diet the patients lost up to 5 kg. (11 lb.) in weight in six months, but when in 1943 the diet was increased all round by about 25% most of the losses in weight were restored in six months.

Prof. J. R. MARRACK emphasized the danger of a deficiency of vitamin B, if a return were made to the white loaf. He also asked whether there was any possibility that mental patients were more susceptible to vitamin deficiencies than other people. Dr. S. W. HARDWICK stated that he saw 12 cases of pellagra in a mental hospital in 1942. Dr. JOSIAH OLDFIELD said that dietaries should be built upon instinct and experience, not upon exact figures for calories. In mental hospitals the officers never ate with the patients and were unaware how much food was wasted. Wastage in cooking should also be investigated. To say that patients should be given 3,000 calories was valueless. Dr. R. STROM-OLSEN spoke of administrative difficulties in the distribution of food. In 1941 at his hospital there was an outbreak of what proved to be scurvy. It was cured by the administration of ascorbic acid, but it indicated that the overheating of food in hot containers in institutional feeding might give rise to vitamin deficiency. Dr. BENESH said that vitamin B deficiencies occurred in mental hospitals, but it was possible that the requirement of the mental patient for vitamin B was specially high. On the other hand, the food habits of the mental patient were often faulty.

The PRESIDENT said that the question of diet was a vital but much-neglected subject in hospitals. Food ought to be looked forward to by the patients, and, generally speaking, that was not the case. There was need for more collaboration with expert dietitians.

STRESS INCONTINENCE

At a meeting of the North of England Obstetrical and Gynaecological Society in Manchester on Nov. 16 Mr. P. MALPAS (Liverpool) read a paper on the cystometric and radiological aspects of stress incontinence.

The outstanding feature of the behaviour of the bladder was its complete and ready adaptation to all conditions of distension, artificial as well as natural, so that its resting pressure remained constant whatever its volume, except during a short refractory phase at the beginning of filling and just before the limit of complete distension. The resting pressure was quite low, but varied in different types of patient, and this variation might afford a method of measuring the essential vesical tone. Thus in early pregnancy the tone, as shown by a high resting pressure, was greater than in the non-pregnant woman. This would appear to be the cause of the frequency in early pregnancy rather than any mechanical factor, and also would appear to be a possible factor in the production of the hydro-ureter of pregnancy. In non-parous women the pressure was usually near to zero, never more than 10 cm. of water, and was no higher in patients with stress incontinence than in other women. This had some bearing on the operative treatment of stress incontinence. The strength of the repair required to produce continence need only be such as to withstand this low resting pressure, which was in no way comparable with the rise in pressure accompanying micturition.

It might be argued that in the various straining efforts which caused stress incontinence the bladder pressure rose to a much greater height, but the evidence did not support this view; even with a paroxysm of coughing it was impossible to build up the intravesical pressure to more than 15 cm. of water. A single cough produced a small rise, but if the cough were repeated quickly enough a summation effect of this degree might be produced. This observation confirmed the view that the mechanism to maintain continence need only be strong enough to withstand a low pressure. No relation existed

between the degree of distension of the bladder and the incidence of stress incontinence. The symptom was just as evident, sometimes more so, when the bladder was empty as at full distension, conforming with the clinical observation that the symptom was often quite troublesome soon after the bladder had been emptied voluntarily, in fact, owing to the pressure of the refractory phre at the beginning of distension it might be more so. As a minor way of combating the symptom he advised these patients to refrain from any sudden effort for a short period after micturition. In stress incontinence the control of micturition itself was normal and patients were able to stop the flow immediately they desired—an observation supporting the view that the lesion responsible for the stress incontinence was extrinsic to the bladder neck and the urethra. One group in which the jet escaped under pressure, and a second and smaller group, in which the urine leaked on any sort of effort, not necessarily an effort raising the intra-abdominal pressure, might be distinguished by the fact that in the first group the ordinary methods of repair proved adequate in the second group more specialized methods might be required.

A lateral cystogram gave much more information than an antero-posterior film, because the vesico-urethral junction was higher than the most dependent part of the bladder and could not be seen except in a lateral view. If changes in the contour of the bladder were to be seen, a weaker solution of sodium iodide than that usually employed was preferable, so the variations in the density of the shadow due to variations in the diameter of the bladder could then be picked out. In the descent of the bladder on straining noted in cases of cystocele and stress incontinence, the bladder appeared to descend as a whole. The vesico-urethral junction was situated far more in the mid-pelvis than was commonly supposed, this had a bearing on the operative repair of these cases. It was important to avoid any operative procedure which would approximate the bladder neck to the back of the symphysis. In many cases in which a repair operation had failed to relieve stress incontinence it would be found that this had been done—the urethra and anterior vaginal walls were closely applied to the back of the symphysis and had lost their normal curve. The good results sometimes obtained by a Goebbel-Stoeckel-Aldridge fascial sling operation were probably due to the fact that the operation ensured an upward rather than a forward displacement, but with great care it was possible to achieve this end by means of the more conventional techniques.

Finally, Mr Malpas showed a series of lateral radiographs taken during pregnancy and labour, mainly illustrating two points: the normal appearances and their variations from the non-pregnant condition and the significance of an "abdominal bladder" during the first stage of labour. In most cases of trial labour in which an "abdominal" bladder could be seen during the first stage, the bladder shadow being completely above the pelvic brim a Caesarean section would be necessary. In a normal labour the elevation of the bladder into the abdomen occurred quite late in the second stage, and even then was often incomplete in cases of easy labour. There was much to be said for combining the lateral radiograph with a lateral cystogram in the course of a trial labour.

Secondary Carcinoma of the Vulva

Prof T. N. A. JEFFCOATE reported a case of carcinoma of the vulva secondary to a primary growth in the breast. The patient was a nulliparous widow, aged 65, first seen in Oct., 1944, complaining of a small swelling in the groin, which she had had for the past six months. This had given rise to an occasional pricking sensation on walking. A little haematuria had been noted two months previously for two days. A radical mastectomy had been performed eight years before for carcinoma. The site of the scar showed no sign of recurrence either in the skin or in the axilla.

On examination the patient looked well, she was thin but did not show any obvious signs of loss of weight. Just lateral to the left pubic spine was a shallow ulcer covering an area of about that of a sixpence, with a serpiginous outline. Its base was rather hard but freely mobile on deep structures, the edges slightly raised. It had the appearance of umbilication. There was no enlargement of the glands in the groin. Beneath the skin of the left labium majus the position of Bartholin's glands a nodule

about the size of a pea could be felt. This was also mobile on deep structures, but was fixed to skin. The patient was admitted to hospital for investigations. The Wassermann was negative. A local excision was performed of the ulcer and nodule in view of the possibility of its being an intradermal carcinoma. Cystoscopy revealed an area on the right bladder wall the appearance of which was identical with that of the ulcer, about the same size and uniloculated. X-ray examination of the chest showed the lower lobe to be collapsed. Histological examination revealed that both lesions were probably metastatic growths, the primary being the previous breast carcinoma.

No further treatment was possible and the patient was kept under observation. Death occurred in 1945. The post-mortem examination showed widespread small metastatic growths, all secondary to the old breast carcinoma, the distribution was bizarre in the extreme, and involved parietal and visceral peritoneum, stomach muscle, the pancreas and even the appendix, both adrenals, the sternum, ribs, and vertebrae, both submaxillary glands, both ovaries, and the left Fallopian tube. It would seem that the secondaries appeared first in the mediastinal glands and were then disseminated in the blood stream. The extraordinary feature was that the vulva was chosen as the site of the first metastasis to attract attention, and that the patient's deterioration was so slow in view of the blood-borne spread.

Fatal Air Embolism in Pregnancy

Dr C. H. WALSH read a paper on fatal air embolism following vaginal insufflation during pregnancy.

The patient, a primigravida aged 17, was being treated by picric acid insufflations for leucorrhoea at about the thirtieth week of pregnancy. The first insufflation produced no discomfort, but the second a week later was followed by disaster. Insufflation was performed by a nurse with the patient lying in the left lateral position. Six or seven squeezes of the bulb were made. In a matter of seconds the patient became cyanosed, fought for breath, and became unconscious, dying in four or five minutes. Post-mortem examination revealed the uterus to be 30 to 31 weeks pregnant and to contain a normally developed foetus. The placenta was situated in the posterior upper segment and showed a small detachment at its lower border and stripping of the membranes down to the cervix, with a minute trace of picric acid powder in a maternal sinus. The inferior vena cava was ballooned with air and the right auricle markedly dilated and containing frothy blood. No other abnormality was observed in any other structure in the body. The immediate cause of death was pulmonary artery obstruction and right-sided heart failure due to air embolism.

It was pointed out that the insufflator delivered about 50 c.c.m. of air and powder, and in the average vagina, if the rubber cone made an airtight connexion with the introitus six or seven squeezes would blow in some 350 c.c.m. of air and powder, delivered at a pressure of at least 150 mm. Under these conditions even a small patent venule was capable of gobbling up air with fatal consequences. Some very interesting radiographs of intravasation of lipiodol occurring in the course of tubal patency tests were shown. The conclusions were mainly that the forcing of air under pressure into any cavity in the body might cause sudden death from air embolism. Pregnancy or a bleeding surface favoured air entry. Therefore it was suggested that vaginal insufflation was contraindicated in pregnancy or in the presence of bleeding from the uterus, and that tubal insufflation should be discarded in favour of lipiodol technique.

* Air embolism in pregnancy was the subject of a question and answer in the *Journal* of Dec. 1 (p. 793).

DUTCH PHARMACY UNDER THE NAZIS

Pharmaceutical conditions in Holland under the German occupation were reviewed in a lecture to members of the Pharmaceutical Society of Great Britain on Dec. 13 by Dr C. J. BLOK, chief pharmacist to the University and Municipal Hospitals, Amsterdam.

About 1943, said Dr Blok, many articles became so scarce that the General Office of Public Health found it necessary to limit the prescribing of the doctors. Cod-liver oil was only to be prescribed for tuberculosis, atropine only for Parkinsonism and as eyedrops, pilocarpine only for eyedrops, luminal only for epilepsy, ropan for serious stomach cases, dermatol only for epilepsy. After the Germans had robbed the safe of the Organon factories insulin also

became very scarce. Dr. Blok went into considerable detail regarding the means taken to economize alkaloids for eye treatment, including the use of ointments instead of solutions. On top of all their troubles, he said, in September, 1944, came the loss of gas and electricity, which meant that sterilization in operating rooms by heat had to be reduced to a minimum as the spirit and petrol which might have been employed were very scarce. Fortunately he himself had steam autoclaves by which sterile injections could still be prepared. Operating rooms had to resort to chemical sterilization with 4% lysol, or a mixture of borax carbol-formalin with a little sodium nitrite against rusting. A very stable solution with quite effective sterilizing powers was 2% formalin, 2.5% phenol, 1.5% borax. Another difficulty was lack of gas for melting ampoule glass. They overcame that by rigging an ordinary bottle with a tube and separatory funnel and putting calcium carbide in it. The temperature obtained was enough to melt glass, and they used the apparatus at home as a lamp.

Correspondence

Tropical Medicine in the United Kingdom

SIR,—Dr. C. M. Wenyon, in his presidential address to the Royal Society of Tropical Medicine and Hygiene, reported in the *Journal* of Dec. 1 (p. 774), has called attention to the inadequacy of the facilities for the treatment of tropical diseases and for clinical research into them in London. He made it clear that, by comparison with the standards of other countries, they were inadequate before the war, and I am sure that your correspondents, Dr. A. R. D. Adams and others (Dec. 22, p. 895), will forgive me for saying that by those standards they were inadequate throughout the United Kingdom. By the fortunes of war they have been expanded in Liverpool and have deteriorated in London, but this is no reason why development should be restricted to London alone, though it is most pressing needed there.

It should be made clear that the deterioration in London is solely one of clinical facilities as a result of the closure of the old Tropical Diseases Hospital, originally following the demand for evacuation of hospitals from London and later due to enemy action. The other activities of the London School have suffered no more curtailment than was necessitated by the departure of many of the staff to the Services, where they have practised their various specialties and gained fresh experience. Now they are returning there is in London a group of very active and experienced workers in tropical medicine and its associated subjects with reasonable facilities at their disposal, except for the lack of a permanent hospital. A temporary arrangement for access to cases for teaching purposes has been made by the courtesy of the Ministry of Pensions, but this cannot meet all the needs of London.

Before the war our chief competitor in the field of research in tropical medicine was Germany. This is no longer the case, but already the United States and Canada have greatly increased the number and quality of their research and teaching institutions so that the United Kingdom now suffers by comparison with them. Apart from the need to treat our own nationals suffering from tropical diseases, it is of great importance that we maintain a high standard of research and teaching, partly for the benefit of the Colonial Empire, and partly because it is very much to the material advantage of this country that people over-seas should look to it as a centre of learning. There is already a tendency for postgraduate students from the Dominions to prefer to go to the United States for advanced study of other branches of medicine, and with them they take very much more than their immediate student fees. This has not yet happened in the case of tropical medicine, but it will happen very soon if conditions do not improve in the United Kingdom.

Dr. Wenyon's proposals therefore merit serious and immediate consideration, but not necessarily acceptance in the exact form in which he puts them. They must be integrated with a scheme taking account of the needs of the entire country, as your recent correspondents suggest, and the proposal for the divorce of the London School of Tropical Medicine from the School of Hygiene, with which it is now incorporated as the

London School of Hygiene and Tropical Medicine, must be subjected to constructive criticism. Further, they must be considered in relation to proposals for the establishment of over-sea laboratories in which workers from them could carry out work that cannot be done in this country.

Proposals of this nature were put forward about a year ago by Brig. Hamilton Fairley and received immediate influential support, but have been fruitless because the machinery to implement them was inadequate. Machinery is now required to prepare a general scheme to cover the needs of Britain and the Colonial Empire, as well as to prepare a detailed scheme for the re-establishment of London institutions to fit into it. There is no more representative body than the Royal Society of Tropical Medicine and Hygiene, and it is to be hoped that Dr. Wenyon's address will have this result. Any resulting scheme will need financial support, the justification for which must be recognized.—I am, etc.,

Ross Institute of Tropical Hygiene,
London, W.C.1.

G. MACDONALD

Latent Disease in Far East P.O.W.s

SIR,—I read with considerable interest Dr. F. E. de W. Cayley's letter on this subject (Dec. 8, p. 822). One must assume that his warning is addressed mainly to those practitioners who sit on medical boards for the Ministry of Pensions, as he refers rather to the desirability of seeing that these returned P.O.W.s "have a square deal as regards financial compensation" than to the need for giving them appropriate treatment. The warning is perhaps not untimely, but there are several points in his letter that seem to me to be misleading, at least in implication.

1. The finding of *Entamoeba histolytica* in the stools of 13% of the men examined is not surprising in view of the fact that about 10% of presumably healthy persons in the United States are similarly infected, and that the figure for the United Kingdom is probably not much less, as shortly after the last war one of our leading protozoologists estimated that between 7 and 10% of the population in this country had *E. histolytica* cysts in their stools. In the absence of physical signs or other evidence of bowel ulceration or of hepatitis, the presence of *E. histolytica* does not constitute a pensionable disability, nor is it necessarily an indication for specific treatment. Conversely, the failure to find *E. histolytica* cysts in the stools does not exclude active amoebiasis even in the bowel, and certainly not in the liver, as in less than 50% of cases of amoebic liver abscess are cysts found in the stools.

2. The pathogenicity of trichomonas, provided it remains in the male intestinal tract, is very questionable.

3. Ankylostomiasis is easily cured and calls for treatment rather than a pension.

4. The statement that "chronic malaria seems to have responded in most cases to the six-weeks prophylactic course" is again very misleading. It is true that a six-weeks course of mepacrine will cure malignant tertian (*Plasmodium falciparum*) malaria, but the troublesome relapsing benign tertian (*P. vivax*), to which Dr. Cayley is presumably referring when he writes "chronic malaria," is emphatically not likely to be cured by a six-weeks, or even a six-months, prophylactic course of mepacrine. Such a course will protect the individual from a clinical attack of malaria only so long as he is taking the drug and for a week or so afterwards while the mepacrine blood concentration remains above the suppressive level (about 12 µg per litre), but after this the patient is liable at any time within a year or even longer to suffer a clinical attack of malaria.

Prolonging the course of mepacrine only postpones the evil day when relapses have to be faced. From the point of view of the Army, it is no doubt good policy to give this six-weeks course of mepacrine to the home-coming P.O.W., as it keeps the man free from malaria as long as he is in uniform, but, from the point of view both of the individual and of the pension authorities, it is not nearly so good; for, on the one hand, the man's first post-war job may be repeatedly interrupted by bouts of malaria and, on the other, as his future malaria relapses are unpredictable the pensions authorities are presented with a very difficult problem in assessment. It would be far more satisfactory if after the last possible exposure to infection the

prophylactic mepacrine were to be given for not more than two weeks (which would allow for the eradication of the more dangerous malignant tertian infection if he happened to have it). Any suppressed benign tertian infection that he had would then be unmasked, he could receive treatment for the early relapses while still in the Army, and meanwhile some indication—by the lengthening of the interval between the relapses, for example—may have been given as to what will be the future course of his infection. This will allow the man to arrange his life accordingly and help the Ministry of Pensions to compensate him more suitably.—I am, etc.,

Silchester.

L. EVERARD NAPIER.

Toxicity of D.D.T. to Man

SIR.—In a medical memorandum entitled "A Case of D.D.T. Poisoning in Man" in the *Journal of April 14, 1945* (p. 517), Dr. V. B. Wigglesworth records the case history of a laboratory worker who exposed his hands to D.D.T. in acetone solution. This case was of particular interest here as certain aspects of D.D.T. toxicity to human beings were being investigated at that time. The conditions of exposure were initiated by volunteers, though the duration and frequency of the exposures used here were probably greater than those of Wigglesworth's case.

The exposures were made in two parts: first, repeated minor exposures, and, secondly, more complete exposures by kneading in the minor exposures 5 c.cm. of 20% commercial D.D.T. 59% p.p. isomer) solution in acetone was poured over the back of each hand, allowed to evaporate, and the residual deposit rubbed off with cotton-wool soaked in acetone and the application then repeated. Five applications were made each morning and each afternoon for two days, the last deposit being left on until the hands were washed for taking meals. Thus the total amount of D.D.T. so applied was 40 g. and the hands were covered with D.D.T. deposit for about 10 hours in all. In the more complete exposures, begun 3 days later, 25 g. D.D.T. dissolved in 200 c.cm. acetone was added to 400 g. soap-stone or French chalk and the mixture kneaded with the hands for 15 minutes, adding more acetone as required. During this operation the mixture completely covered the hands almost to the wrists. When the hands were taken from the mixture the solvent rapidly evaporated, leaving a dry deposit on the skin, which was removed as before by swabbing with acetone. Finally another kneading exposure lasting 30 minutes was carried out 1 to 2 weeks later. Three volunteers did the entire experiment, and a further three did the kneading exposures only. None of the volunteers suffered any irritant or toxic effects at all.

In Wigglesworth's case symptoms commenced one to ten days after exposure; the patient developed a feeling of heaviness and aching in all the limbs and weakness of the legs, and spasms of extreme nervous tension. There was some improvement during a holiday taken at this time; but on returning to work the condition deteriorated, and some three weeks later the perpetual ching in the limbs confined the patient to bed. Sleep became almost impossible; the feeling of extreme nervous tension became more frequent, and a state of acute mental anxiety developed. About six days after being confined to bed involuntary muscular tremors occurred over the whole body, and these were experienced on at least two subsequent occasions. After 10 to 14 days the patient got up, although the aching in the limbs was still severe. His recovery was very slow. He was away from work for 10 weeks in all, but even at the end of a year recovery was not quite complete.

In view of the negative results obtained here and of the fact that many symptoms but no signs apart from muscular tremors developed in Wigglesworth's case, it seems possible that the patient was suffering from an anxiety state and that D.D.T. in acetone is not a particularly toxic preparation. It may be added that many other experiments in which moderate quantities of other preparations of D.D.T. have been applied to the skin have failed to produce toxic signs or symptoms, although in some cases irritancy due to the vehicle has occurred.—I am, etc.,

** An investigation into the toxic effects of a distemper containing D.D.T. and a fatal case of D.D.T. poisoning are described in the *Journal of Dec. 15* (pp. 842, 845).—Ed., B.M.J.

Acute Yellow Atrophy after Trilene

SIR.—In his letter (Dec. 1, p. 784) regarding Major K. N. Herdman's case of acute yellow atrophy, Dr. Philip Ayre states that the short-acting barbiturates are almost entirely detoxicated in the liver, quoting Dr. Langton Hower's reference to the work of Reynolds (1938) *et al.* and the general assumption regarding their fate arising from Tatum (1939) and Goodman and Gilman (1940). Hale (1935) and Marshall (1939) have also attributed detoxication to the liver, but Cameron and de Saram (1939), Scheffley and Higgins (1940), and Kohn-Richards and Grimes (1939) were unable to confirm this, though Kohn-Richards and Grimes definitely showed that detoxication does take place in the body. Masson and Beland (1945) suggest that the barbiturates can be divided into four groups according to their site of inactivation or excretion, and these workers attribute detoxication of pentothal to the body tissues generally and not to any great extent to the liver and kidneys. Evipan, however, falls into the group mainly inactivated by the liver.

Whatever value may be placed on experimental work, the actual fate of various barbiturates in the human body remains for the most part unproven, and accordingly the anaesthetist must still proceed with blind caution; but it seems probable that fallacies will arise from attempts to draw conclusions about the barbiturates generally from work upon isolated members of the group. All too often experimental work has little relation to the procedure and dosage of clinical anaesthesia, as is instanced by Beecher's (1938) statement on the similarity of the gross effects of chloroform and ether—effects which we do not promote with the latter agent because we do not employ either in sufficiently high concentrations.

Lundy and Adams (1940) and Masson and Beland (1945) state that from clinical experience they have found little contraindication to the use of pentothal in liver and kidney disease, though Argy *et al.* (1936), Goodman and Gilman (1940), and Kohn-Richards and Appel (1941) have all shown that where the liver or kidney is the organ mainly responsible for inactivation or excretion, sensitivity to the barbiturates is greatly increased. Using routine hospital investigations, I have been unable to prove any impairment of the liver or kidney function on a few patients found to be hypersensitive to pentothal, and though admittedly the dosage of pentothal administered to patients with active liver disease has been very low, none has shown an indication of hypersensitivity.

So far as the cause of acute yellow atrophy, the subject of the original letter, is concerned, I should like to associate myself with Dr. Clifford Wilson's theory (Dec. 1, p. 784)—I am, etc.,

Renal Failure and Anoxia

SIR.—In a recent article Macgrath *et al.* (1945) proposed that the title "renal anoxia" be applied to the renal failure occurring in a variety of conditions "generally secondary to acute peripheral circulatory failure." As my name (Tomp. 1942a) has been prominently and inaccurately identified by the authors with the proposed title, I shall be much obliged if I may be permitted to make some observations concerning it.

In 1941 (a) I first put forward the suggestion that the anuria of cholera is due to anoxia in these words:

"The frequent failure of intravenous saline injections to restore and maintain the circulation in cholera, as well as to re-establish the secretion of urine after collapse has existed for two or more hours, is thus seen to be due to irreparable damage to the capillaries."

endothelium, as well as to the epithelial cells of the kidney tubules, from lack of oxygen."

In the same year (1941b) and also in 1942 (a) I gave reasons for believing that the anuria of "crush injury" is, like the anuria of cholera, due to anoxia.

In the first of these two articles I wrote:

"It would therefore appear that, in so-called 'crush injury,' the renal failure and associated histological changes in the tubules are caused solely by oxygen want (as suggested by Sir L. Hill), the epithelial cells of the convoluted tubules being even more sensitive to want of oxygen than the endothelium of the blood capillaries itself."

In 1942 (b and c) I gave a detailed analysis of the causes of anoxia and suggested that the anuria found in blackwater fever, incompatible blood transfusion, and pernicious anaemia, as well as in cholera and "crush injury," is due to anoxia.

In 1943 these various communications were finally summarized by me in an article in which I concluded that "the anuria and renal changes met with in crush injury are manifestations of anoxia due to traumatic shock, and are identical in origin with those found in acute haemolyses—e.g., incompatible blood transfusion and blackwater fever; in pernicious anaemia, severe haemorrhage, and the collapse of cholera, all of which are due to anoxia."

With regard to incompatible blood transfusion, it would appear that the renal syndrome found in this condition is not ordinarily due to the anoxia caused by haemolysis of the recipient cells, but to anoxia caused by collapse (Foy *et al.*, 1943), or by the antecedent conditions necessitating transfusion (haemorrhage, anaemia, etc.).

In the 1943 (4th) editions of the textbooks of pathology by Beatty and Dixon and by Boyd the importance of anoxia is stressed as a cause of fatty degeneration, particularly of the secretory cells of the kidney and liver. Of anoxia Boyd (1943) writes as follows: "There are two great causes of fatty degeneration: (1) the action of toxins and (2) the lack of oxygen. It is possible that the first acts by virtue of interfering with the proper oxygenation of cells. . . . Insufficient oxygenation . . . is seen in severe anaemias both primary and secondary." Beatty and Dixon also write to the same effect.

Anuria may be caused, apart from obstructions to the urinary tract, (1) by a fall in arterial blood pressure (Winton, 1937) and (2) by damage to the secretory epithelial cells of the renal convoluted tubules from (a) anoxia and (b) inorganic or organic poisons, including bacterial and viral toxins (Leftwich, 1920; Moon, 1944). Since circulatory failure is only one of the many causes of anoxia (Tomb, 1942b, 1942c) and anoxia is only one cause of renal tubular degeneration and failure (Boyd, 1943; Beatty and Dixon, 1943) it is not possible accurately to attribute to anoxia, whether or not due to circulatory failure, the renal syndrome common to the varied conditions enumerated by Maegraith and his associates in their article.—I am, etc.,

Keratoconjunctivitis

SIR.—The paper by Major R. J. Buxton on keratoconjunctivitis (Dec. 15, p. 847) is of considerable interest. Lesions covered by this general term differ widely in aetiology, and it is therefore important to define the description "keratoconjunctivitis" more precisely. For example, superficial punctate keratitis (Fuchs's) is a well-established entity occurring sporadically; during the past 15 years an epidemic form has been recognized with involvement of the conjunctiva, cornea, pre-auricular gland, and with ptosis; and there is satisfactory evidence that the infection is due to a virus. For these reasons

the term "virus keratoconjunctivitis" or "epidemic virus keratoconjunctivitis" has been evolved and is coming into general use. We are not clear if the author is using the term "keratoconjunctivitis" in this sense for some of his cases. In epidemic virus keratoconjunctivitis the corneal opacities are frequently varied in size and distribution, and it is by no means uncommon to find them mainly in the periphery of the cornea as in the cases described by Buxton. The discrimination is an important one, as the search for focal sepsis has little part in the treatment of epidemic virus keratoconjunctivitis, which in the great majority of cases is a self-limiting disease.—We are, etc.,

Operation for Varicose Veins

SIR.—Dr. R. R. Foote (Nov. 3, p. 627) raises the question of the use of sclerosing solutions at the time of the ligation of the varicose veins. It would appear that to omit a sclerosant at the operation is to go back to twenty-five years ago and to disregard a generation of experience in injections of varicose veins. Surely the ideal time to use a sclerosant is when the vein is empty and without circulation. In my hands the combined operation yields consistently good results. Admittedly, it does not sclerose all the varicosities, but certainly the main trunks and their large adjacent branches are rendered solid before the patient leaves the table.

I would stipulate two points about a sclerosing agent. The first is that it must be harmless when injected into the systemic circulation. Saturated solutions of common salt or of glucose fulfil this condition. Other agents—such as ethamolin, sodium morrhuate, sodium salicylate, quinine, lithium salicylate—are capable of lethal effects, and for this reason I have abandoned them at the operation of ligation and injection. Secondly, the sclerosing agent, the syringe and needle must be sterile; this is an obvious point, but it is often neglected and deaths have occurred from septicaemia. Syringes are often "sterilized" in spirit and the sclerosing solution handled in such a way as to contaminate it. Varicose veins are large conduits connected with the main systemic circulation, and any infection introduced into them is quickly distributed. Therefore the technique must be beyond reproach. Because the number of vein patients is large we must organize and train teams to handle them, rather than offer mass-production operations of inferior quality. Already Continental surgeons have visited Britain for information on this ubiquitous condition, and we must give them a sound lead.—I am, etc.,

London, W.1.

HAROLD DODD.

SIR.—Since this disease is under discussion again perhaps I might be permitted to give the details of the technique I have found most satisfactory in many hundreds of Service and civilian patients, both male and female, during the past six years.

My patients are always admitted to hospital for a week at least to ensure satisfactory pre-operative preparation and post-operative care. They are always operated on in the main theatre, with most careful aseptic precautions before, during and after operation, since one is operating in a potentially infected area—the groin. I have never had any delay in the healing of wounds as experienced by some surgeons, and I feel sure this delay in healing must be due to lack of proper asepsis and haemostasis or to escape of sclerosing fluid into the wound (Dr. L. F. Muldavin, Dec. 8, p. 816). As for all other planned operations, I always have the first "skin prep." done the day before operation. The points of technique are as follows:

1. The patient lies supine on the operating table, which is then tilted head down so as to empty the dilated veins as much as possible. We desire to produce an aseptic phlebitis in the injected veins, not a bulky thrombophlebitis.

2. Local analgesia is usually employed, unless the patient desires general anaesthesia, premedication being with omnopon and scopolamine in either case.

3. An oblique incision is made in the skin creases across the saphenous opening, and the upper end of the long saphenous vein is displayed. All the tributaries are isolated, both at the saphenous

opening and along the proximal 2 inches (5 cm) of the main trunk, being then ligated and divided.

4. The long saphenous vein is doubly ligated flush with the femoral vein then divided beyond the ligatures.

5. As ligation alone will not lend to efficient and firm obliteration of the dilated vessel and tributaries in the leg, the distal end is injected with sclerosing fluid through a ureteric catheter passed down inside it as far as possible, sometimes to the medial malleolus. Sodium morrhuate (4 c.c. of 4%) has been found quite satisfactory. The lower end is then doubly ligated to prevent leakage back of sclerosing fluid into the wound.

6. The wound is closed after checking haemostasis and swabbing it out with dilavin, a deep catgut (00) continuous suture being used for the fascia and interrupted vertical mattress sutures of nylon or fishing gut for the skin. These latter are placed close together to ensure careful sealing of the wound against infection or contamination from outside later on.

7. As soon as possible after injection of the saphenous vein crêpe bandages are applied firmly from toes to groin, to prevent filling with blood and dilution of the sclerosing fluid. The dilated veins are far less likely to become recanalized if converted into flat ribbons instead of ugly lumpy masses of clot. I feel this early bandaging to be most important, but I have never seen it referred to by other surgeons.

8. A dressing is applied to the wound, fixed with "elastoplast."

9. The patient is encouraged to walk about the same day and get up quite normally each day afterwards.

10. Further injections are made into any veins in the leg not blocked by the original injection. This is begun about a week or so after operation, and into veins emptied of blood so far as possible by elevation of the leg. The bandages are reapplied and worn until no swelling occurs at ankle or on dorsum of foot with normal activity, usually in two to three weeks. I have had no cases of swelling lasting longer than that.

As Major-Gen. W. H. Ogilvie stated (May 5, p. 619): "The only successful treatment for true varicose veins which are causing symptoms is Trendelenburg's operation, properly done." He condemns injection alone because it is not dealing with the cause—i.e., back-pressure from the femoral vein above due to incompetence of the valves in the long saphenous trunk and its tributaries. This is a *sine qua non* and vitiates the necessity for Trendelenburg's test, or the application of a series of tourniquets (Dr. Muldavin, Dec. 8, p. 816). It also emphasizes the need to divide and ligate the tributaries at and below the saphenous opening. Injection of any dilated and still present calf veins should always succeed then, provided the injection be made into a vein emptied of blood by elevation of the leg and supported later by firm bandaging. If the patient is encouraged to walk about as soon as the bandage is applied following injection, any sclerosing fluid entering the deep veins is soon diluted and swept away without causing damage. I have not had any evidence of such damage occurring in any of my patients.

Surgical excision of calf veins would produce unjustifiable and unsightly disfigurement in a woman, and I have never found it to be necessary even in "Commandos." I can hardly imagine any operative procedure more likely to cause damage to the remaining superficial and communicating veins, with risks of subsequent haemorrhage, sepsis, or permanent venous insufficiency, than the old operation of avulsion of lengths of varicose veins. I have just operated on a woman who had thirteen incisions made over both her legs and thighs for such a barbarous procedure some fifteen years ago, followed by injection of recurrent dilated veins five years ago. She had not had a Trendelenburg operation done, so that her original condition could hardly have been worse than the hideous deformity of her recent recurrent state.

I have not found it necessary to ligate the long saphenous vein at the medial malleolus (Mr. Harold Dodd, June 2, p. 780), nor can I understand the rationale of this procedure, since the venous pressure is from above and not below the malleolus, unless, of course, it is to support the weight of the relatively huge volume of sclerosing fluid he uses. I feel it is safer to take "two bites at the cherry," and inject only 3 to 4 c.c. of sodium morrhuate at a time, with less risk of its escaping into the deep veins and no risk of the "bursting effect from below" on the upper ligatures. I have never found ligation of the long saphenous vein or its tributaries in the leg necessary, but the short saphenous vein may need to be divided and ligated in the medial space. The reported fatalities have been mostly,

if not all, from pulmonary embolism, due to failure to ligate the saphenous trunk flush with the femoral vein.

I agree with Mr. Dodd that most meticulous attention must be paid to detail in performing these operative procedures, which should not be left to the inexperienced H.S. alone. Dr. R. R. Foote (Nov. 3, p. 627) refers to some of the mishaps that might occur. But I cannot agree with him that "economical conditions or shortage of beds" should persuade us to treat these people as out-patients. By keeping them in hospital for at least a week one can observe the immediate result and/or reaction following the ligation and injection operation. Surely it is better to do less work to the best of our ability than more in a slipshod manner. Some people have quite severe and unpredictable reactions from sodium morrhuate injection, even with high pyrexia and rigors. I feel it is safer to have such people in hospital under careful observation.

With reference to the treatment of varicose ulcers (Dr. R. K. Brooks, Dec. 8, p. 816), I have invariably found that dealing with the cause—the varicose veins—is the quickest and most certain way of getting these ulcers to heal. Surely improving the circulation in and around the ulcerated area is far more important than what is applied to the ulcerated surface. "Elastoplast" strapping, Unna's paste, or "vircopaste" bandages all seem equally efficient in aiding healing, provided the cause is dealt with first. Some people cannot tolerate "elastoplast." I know of only one patient whose ulcer obstinately refused to heal after dealing with her varicose veins, and it had to be excised—I am, etc.

MOULTON VERNON HOSPITAL,
NORTHWOOD

ALAN SHOTTEP.

Cardiac Massage

SIR,—Being in a position to record three consecutive recoveries from impending death under anaesthesia goes some way towards simplifying a plan of action for use in case of cardiac arrest. I have been able to satisfy myself that the early anxieties and later complications that follow temporary cardiac cessation are directly proportional to the length of time the organ is functionless—an observation in keeping with rudimentary physiological principles and common sense. I can go so far as to say that now that prophylactic chemotherapy is available, should the time the heart is allowed to stand still be less than 15 minutes it is improbable that the patient will suffer harm or even any inconvenience over and above that occasioned by an upper abdominal incision.

The anaesthetist reports that he cannot feel the pulse. When the surgeon has access to a large artery—e.g. the abdominal aorta—the common iliac—he can himself confirm that the heart has ceased to beat. When a large artery is not available the surgeon must wait not more than three-quarters of a minute while the anaesthetist verifies that the patient has an unobstructed airway, after which the anaesthetist gives the final vital verdict. While the fleeting seconds are passing the surgeon is not idle; he and the theatre sister are sterilizing the epigastric area and arranging towels suitably. At the given word, with a sweep of the knife the upper abdomen is entered in the middle line immediately beneath the xiphisternum. The heart is massaged beneath the diaphragm, with counter-pressure exerted by the left hand on the lower thorax. Directly the welcome response is assured, sulphathiazole powder is poured into the wound, which is closed rapidly. As soon as convenient the blood pressure is taken; if it is under 100 mm. Hg, plasma infusion is started and methedrine administered. Prophylactic penicillin therapy is commenced in the early post-operative period. The whole point of this communication is that I want to make it perfectly clear that I have abandoned expending time in performing artificial respiration and injecting adrenaline into the ventricle.

I would also like to emphasize that experience has taught me that cardiac arrest can occur in any patient, with any anaesthetic agent, and with any anaesthetist. To those who question this statement (and the correspondence columns of the *Journal* show that there are many) I suggest that if the coroner for the district be consulted it is probable that "he who thinketh he standeth will take heed lest he fall from unpreparedness."—I am, etc.,

LONDON, W.1.

HAMILTON BAILEY.

Non-specific Mesenteric Lymphadenitis

SIR,—With reference to Mr. Ian Aird's instructive article on acute non-specific mesenteric adenitis (Nov. 17, p. 680), I should like to record two interesting cases treated in this hospital during the past six months.

Case 1.—A boy of 13, sent in as a case of perforated appendix, complained of nausea for four days but no vomiting, diarrhoea one day, and acute lower abdominal pain starting early on the day of admission. No previous attacks. On examination he was obviously ill, temperature 100.6°, pulse 112, tongue moderately furred. Abdomen tender all over and rigid in the lower half; the tenderness was most marked to the left and slightly below the umbilicus, and beneath the rigidity an indefinite mass could be made out at this point. P.R. there was a boggy mass, but no definite pelvic swelling, and no tenderness.

With a provisional diagnosis of peritonitis due to an inflamed Meckel's diverticulum, or perhaps the rare left-sided appendix, he was opened through a paramedian incision. There was a large quantity of frankly purulent fluid in the peritoneal cavity, and the whole of the mesentery of the small intestine was studded with large fleshy glands. They were soft with no evidence of caseation, and varied in size from 1/2 to 2 in. (1.25 to 5 cm.), the majority being about 1 in. (2.5 cm.) in diameter. The largest was at least 2 in. in diameter, and was acutely inflamed, red, and fluctuant, and had become firmly adherent to the upper part of the descending colon, with which it had formed a faecal fistula. No primary cause was found for these enlarged glands. The appendix was normal, as also was the whole of the bowel wall. A temporary transverse colostomy was performed proximal to the faecal fistula, and the pelvis drained through a separate stab incision; 10 g. sulphanilamide powder was sprinkled into the peritoneum, and the wound closed. The appendix was not removed. After a rough passage for the first two or three days he began to improve, and the colostomy was closed a fortnight later, after which he made an uninterrupted recovery.

The pathological report on a typical medium-sized gland removed at operation for biopsy was as follows: "Great endothelial hyperplasia with polymorph infiltration. Acute sinus catarrh."

Case 2.—A man of 62, admitted as a case of subacute intestinal obstruction, complaining of central abdominal pain for 3 days and vomiting for 2 days. Bowels constipated. He had had several previous attacks of less severity. On examination he appeared comfortable, temperature 97.6°, pulse 76. Apart from some very mild lower abdominal tenderness there was nothing abnormal to be found. An enema gave him relief and he slept fairly well through the night. Next day he said the pains were getting worse, and his temperature had risen to 99.4°. The abdominal tenderness was more marked, but was not localized, and there was no rigidity.

With the diagnosis still very much in doubt he was opened through a paramedian incision. There was a localized pelvic peritonitis present, caused by the rupture of a small mesenteric gland. The mesentery of the small intestine contained a considerable number of small fleshy glands, about the size of a pea. One of these, about 1 in. (2.5 cm.) from the bowel and 6 in. (15 cm.) from the ileo-caecal junction, had become completely necrotic and had ruptured, causing the peritonitis, and leaving a hole filled with slough. There was no evidence of diverticulitis, and the wall of the small intestine was normal. The appendix was also normal but was removed. Sulphanilamide powder was sprinkled into the peritoneum and the pelvis drained. Convalescence was protracted by the development of a subphrenic abscess which had to be drained, but he eventually made a complete recovery.

These two cases are recorded as examples of the more serious complications of acute non-specific mesenteric adenitis. Many have probably had similar cases, but they are seldom mentioned in the textbooks.

I should like to thank Dr. W. Briggs and Mr. Pearce for permission to publish these cases.—I am, etc.,

JANET W. BEDFORD,
Resident Surgical Officer.

Blackburn and East Lancs Royal Infirmary.

Epidemic Diarrhoea and Vomiting

SIR,—Your issues of Oct. 20 (p. 524) and of Nov. 10 (p. 666) and others lead me to report on my experiences on the above subject. In the last eight years there have been recurrent outbreaks of this complaint in this district, and I crave permission to offer my explanations.

(1) Like the other observers, I have found that repeated examinations of stools have produced no organisms which stand out as being chief offenders. This, then, makes me think a virus is responsible.

(2) This virus does not act by itself, but by a process of symbiosis—i.e., in combination with other commensals of the bowel, both being necessary to produce the symptoms. In this

way one can attempt to explain why certain members of the household escape and why the complaint "shows up" in isolated places miles apart.

(3) There is a seasonal incidence, for it has been my observation that the malady prevails in very wet weather. This weather produces a richer type of grass, which is fuller of sap. This has an effect on the quality of milk, for I am of the opinion that milk is the vehicle through which the germ is carried; and cows' milk is not the only vehicle, for I have known at least two cases in which breast-fed babies have had the complaint while the mothers were victims.

(4) Finally, I have observed on more than one occasion that 48 hours or so after an attack of vomiting, diarrhoea, and abdominal pain, jaundice appeared, and in epidemic form. I offer the suggestion as well, that there is some connexion between this (fortunately) generally mild complaint and the so-called more serious summer diarrhoea of children.—I am, etc.,

Chipping Sodbury.

ROSS. K. BROOKS.

Domiciliary Midwifery and the Family Doctor

SIR,—It is unfortunate that owing to the time taken by ocean mails in these days the subject of this letter may well be "dead bird" by the time it reaches you. The letters in *Journal* during last September on doctors and domiciliary midwifery have interested me, and I felt that I would like to point out that there is not necessarily any conflict between the two views. It is only when one is bound to things as they are that there appears to be any. I may say that I am no stranger to English ways, having learned my midwifery in the neighbourhood of Camden Town and Somers Town.

I would like to illustrate what I mean by giving you a short description of midwifery as it is carried out in a country town in Australia, which does not differ in any essential from other country towns except that it has achieved a concentration of hospital resources. The town and district comprise about 15,000 people and are served by six general practitioners. There is only one hospital in the town, a 100-bed community hospital. Its maternity section is a unit capable of taking up to 25 patients in single-room, double-room, and ward accommodation. Some 300 to 400 maternity cases are attended in the unit each year by the six doctors, no resident being employed. This is surely ordinary enough for anyone. The points bearing on the argument of private practitioner *versus* hospital for midwifery are these:

1. The doctors have been so convinced of the superiority of proper hospital accommodation for delivery that for years they have refused to attend any confinements except in the hospital.

2. The patients have become equally convinced. Some years ago there were five posts at distances of from twenty to fifty miles (30 to 80 km.) from the town staffed by certificated midwives under the Bush Nursing Association. Four of the five have closed down for lack of support. In the fifth unit, where a nurse does no confinements, the patients coming fifty miles to this town for hospital conditions.

3. Practically all pregnant women consult their own doctor in the early stages of their pregnancy, and attend the doctor regularly for ante-natal care at their own professional room (which in this town are all under the hospital roof).

4. All women in labour and during the puerperium are attended by their own doctors with the assistance of the trained nursing staff of the hospital.

5. In any emergency the full resources of a properly equipped hospital are at the disposal of the patient.

6. All babies, including premature ones, are nursed in the unit nursery in suitable conditions, including a separate room if necessary; and after leaving the hospital they are cared for by the Baby Health Centre sister, who makes contact with the mothers while they are in hospital.

7. The seven double-certificated sisters on the unit staff are able to give a better service to all mothers than would double their number if they were scattered round the district on a domiciliary service.

8. All morbidity is known, checked, watched, and discussed, and check swabbing of throats and bacteriological examination of hands can be carried out at need.

9 Proper records of all work done can be kept on a truly comparable basis, and this has proved of great value in the past

10 A full clinical survey of ten years' work in this unit has been drawn up. It shows that the results in all respects are of good standard in comparison with the main teaching hospitals of the State

The arrangement is simple and effective. It involves no departure from established principles. It is a true fusion of the functions of the family doctor and the maternity hospital. It requires no more than the provision of the necessary accommodation and staff, together with the putting into effect of the principle that doctor and hospital are properly one unit and not to be dissociated from one another—I am, etc.

ARTHUR E. BROWN

Spinal Analgesia in Operative Obstetrics

SIR,—As regards spinal analgesia and the correspondence of the last few weeks on this subject, I would like to say that I have had the utmost satisfaction in the use of light percaine and nupercaine given by the Etherington Wilson technique. It is agreed I think that the utmost attention to detail is necessary for success with spinal analgesia, not only in the technique of administration but also in the giving of epinephrine, the greatest gentleness in handling the patient, and keeping the head low for 24 to 48 hours—the longer the better—to avoid headache.

I have used the heavy percaine on only a few occasions, and in two comparatively minor operations in men—circumcision and anal abscess—headache followed. I therefore never use it now, and I would suggest that Dr Louis Resnick (Nov 24, p 722) would do better to use the light percaine with the rest of his article. I am in complete agreement. The beautiful relaxation which one gets in all lower abdominal work under spinal analgesia more than counterbalances any disadvantages.

In the same issue (p 719) Mr Alexander Lyall reviews 80 cases of appendicitis, and in discussing the anaesthetic used there is not even mention of spinal. I would say that one should ask oneself, in every case of appendicitis, Are there any reasons why a spinal analgesic should not be used as the best? I consider 13 or 14 ccm is a very safe dose in practically every case, no matter how ill the patient may be (and it is particularly good in children), with proper premedication of omnopon and scopolamine. Especially do I say this because Mr Lyall says more than 80% of the anaesthetics were administered by house surgeons. Therefore, without any disparagement of house surgeons I think it will be agreed that he was often working at great disadvantage. Very good relaxation is a *sine qua non* in all these cases where tissues are friable, and it is important to reduce trauma to a minimum. And surely, with reference to shock, the anaesthetic that completely stops the painful stimuli from the very sensitive parietal peritoneum is the best to use. Scopolamine, by the way, should only be given in small doses to old people.

Further, I have found that with ether anaesthesia there is much more bleeding, which means prolonging the operation and we cannot deny that with ether chest complications are exceedingly frequent. Indeed, I think it pays the surgeon to give his spinal analgesic himself, having developed his own technique, in this way he can practically always assure for himself an excellent analgesic, unless, of course, there is a skilled anaesthetist available with the necessary apparatus and even then I would prefer to trust my own spinal. While the anaesthetist may have plenty or nothing to do, his presence is essential even if only for the valuable psychological help that he can be to the patient. The criticisms that are levelled against the use of spinal analgesia always appear very theoretical and based on exceptions, which would be a method of damning almost any anaesthetic in the whole list.

Finally, I have often thought that no young doctor should go as a ship surgeon without being master of one technique for the administration of spinal analgesia. He is quite unlikely to have a skilled anaesthetist for an emergency operation, but if he has his spinal he has complete command of the anaesthetic situation even though he may not have had a great deal of experience of, say, acute appendicitis, and things will be easier for him and safer for the patient—I am, etc.

N. BEATTIE

Stethoscope versus X Rays

SIR,—I usually read the "Reports of Societies" with pleasure and profit, but in the *Journal* of Dec 15 (p 836) the report of the meeting of the Section of Medicine of the Royal Society of Medicine on stethoscope v. x rays fills me with dismay and apprehension. That any learned society should discuss a subject under this heading is a mystery beyond my comprehension. It could only be equalled by the surgeons discussing rectal examination v. abdominal palpation. Most of the speakers obviously felt the limitations of the title and included in their remarks the full range of physical examination. Several appear to be thinking in terms of early tuberculosis, in which no one would dispute the pre-eminent value of radiology. It is distressing to read the statements attributed to physicians of repute, the following represent a random selection: "The stethoscope might be very useful as an adjunct to radiology."

It was difficult to avoid going through the gesture of trying to hear vague mysterious sounds. Clinicians, however, should continue to use the stethoscope, because patients expected to see it. Such may be relatively innocuous in debate, if, however, they are deemed suitable for publication they might well be taken as representing the views of speakers most of whom are associated with the teaching of clinical medicine. Should this be the case I can only visualize their students as taking a history (60% importance) wearing a stethoscope for the same decorative reason as a mayor in chain of office then busily signing the requisition for Life-saving help from radiological and pathological colleagues. Thus the future medical services may in fact be staffed by clerks with a medical background.

This slightly exaggerated picture is nearer the actual facts than one likes to see. The essential trouble amongst the recently qualified is that they have not been taught to use the five senses God gave them. Especially is this so in the examination of respiratory disease—admittedly a difficult branch of medicine. I strongly advise senior students and the recently qualified to read Robert Coope's *Diagnosis of the Chest*. It will be a suitable antidote to any unfortunate impression they may have received from the stethoscope v. x rays discussion. Personally I should I fall ill with pneumonia, I hope the colleague who tend me will be armed with clinical nous and a stethoscope, keeping in reserve an exploring needle in case of need—I am, etc.

Brighton

R. C. HUTCHINSON

Physical Therapy in Mental Disorder

SIR,—I am glad to find that once again Dr D. W. Winnicott (Dec 22, p 901) has raised his voice in protest over the craze for physical treatment of mental diseases. Physical methods, medicinal or otherwise, have their place in these cases. But if the trouble be really mental, and not a physical disease with secondary mental symptoms, these methods are at best nothing but palliatives and at worst a real menace.

It is true that psychotherapists have not yet agreed, and probably never will agree, as to the exact aetiology of mental syndromes. But there is one thing which anybody with psychological insight will accept, which is that mental disease starts in the mind—which is not synonymous with the brain and nervous system—and that the physical troubles and the behaviour patterns that accompany them are only the last link in the chain. Thus to talk of "cure" by leucotomy or electrical convulsions is not true. It would be as true to say that one has cured a car crash or the bad habit of scorching by cutting out some of the cylinders of his car as to claim cure by the former, while the latter is very similar to taking a jar of boiled sweets which have stuck together and shaking the jar: the sweets may come unstuck, and they may change their mutual relationship, but the contents of the jar still remain the same, and, sooner or later the unremoved moisture will result in their settling down once again into a sticky lump. Surely it is a case of "rendering unto the body the things that are the body's and unto the mind the things which are the mind's" and of seeking out the causes of disease rather than attempt flashy results—i.e., in the case of mental troubles to treat the mind first and foremost.

Apart from dubious results, moreover, I agree with Dr Winnicott that the drastic methods named above are a menace. I have seen two or three cases of patients already suffering from

shock treated, by practitioners who would probably shy if one suggested that they were using homoeopathy, by further shock. The result has been that instead of having one more or less serious trauma to deal with, one has had to try and deal with the double dose, the second one deliberately inflicted. As to leucotomy, again one wonders whether society is going to be any the better for having more or less decerebrated robots let loose in it, simply because they have been so mutilated as to be incapable of behaving badly.

Many will doubtless agree that medicine is primarily concerned with human beings: not with just one aspect of them, but with the whole man, bodily, psychic, and spiritual. It seems, therefore, that our standards should go further and reach deeper than to judge results merely by the outermost surface of that man—i.e., his behaviour. I suggest that, going beyond Dr. Winnicott's suggested "habeas cerebrum," what is required is "habeas hominem," so that we are not deceived by short-sighted views.—I am, etc.,

London, W.C.1.

L. J. BENDIT.

SIR,—Whatever force there may be in Dr. D. W. Winnicott's protest (Dec. 22, p. 901) against a too-enthusiastic application of physical methods of treatment, such as electrical shock therapy and prefrontal leucotomy, in mental illness—and his protest appears to be only too well justified—there is strong reason to emphasize the need for an adequate appreciation of the psychological background in these cases, the psychological as well as the physical reactions of the patients to the treatment, and the psychotherapeutic requirements of the situation. This caveat would have been unnecessary a few years ago, but there is a perceptible "retreat from psychology" among a section of psychiatrists, both young and old, which, though only a passing phase not unconnected with the war, is likely to be unfortunate for patients while it lasts.—I am, etc.,

London, W.1.

WILLIAM BROWN.

Descent of the Testis

SIR,—Dr. Mary Wood's suggestion (Dec. 15, p. 860) that the descended testis and scrotum of mammals "might be a means of sexual attraction in animals having few other visible sexual differences" is of the greatest interest, but it is difficult to understand how they could function in this way. The lower mammals generally, in contrast to the amphibians, typical reptiles, and birds, have a highly developed olfactory apparatus, including an expanded nasal cavity, numerous conchae, and complex nervous arrangements; and this apparatus is used for finding and following mates and for retrieving the young. Among reptiles, the snakes and lizards also use their sense of smell for finding mates and food, but in these forms it is Jacobson's organ that has been elaborated as the receptor, and it is only in some extinct mammal-like reptiles, related to the mammalian ancestral line, that a complex olfactory apparatus is known to have existed. Associated with these developments are the anal and other scent glands so widespread in the various orders of contemporary mammals. So in primitive mammals the only phase of the sexual cycle in which the scrotum could be of importance as a visual stimulant would lie between the approach, conditioned by scent, and actual contact, and it is difficult to see how it could function effectively.

In those mammals in which smell has become of relatively less importance in mating the scrotum has not become noticeably more conspicuous. In monkeys arboreal life has led to a secondary simplification of the olfactory apparatus and to the loss of the anal glands (though in lemurs the numerous conchae are retained and pairs follow each other and mothers their young through the branches largely by scent). Brightly coloured sexual skin and occasionally phalli and cheeks are found, but the scrotum is not particularly conspicuous. In ruminants the scrotum may certainly be large, but special sexual behaviour and often bodily features such as horns are more striking characters differentiating the sexes. In no group of mammals is there any parallel to the elaboration of form and colour associated with intimidation, courtship, and unpalatability found in the birds and amphibians, where visual, rather than olfactory, considerations are paramount.

In man, where with the thinning of the hair and the fully upright posture the scrotum has become more conspicuous, it

is not that organ which has been chosen for ornamental elaboration: it is rather the breasts (*Homo* is the only genus in which the non-lactating breast remains large and fatty), the buttocks (particularly in the Bushman-Hottentot), the umbilicus (more conspicuous in *Homo* than in other animals equally well provided with subcutaneous fat), and the dimples over the posterior superior iliac spines. Possibly hairlessness itself was conditioned by sexual rather than by natural selection (suppression of vermin). Opinions may differ as to whether, judging from the results, our ancestors showed good aesthetic appreciation and chose their mates well, but there is no evidence that in us or in other mammals the scrotum has played any, particular part as a centre of attraction. The descent of the testis remains one of the mysteries of evolution, in spite of the partial solution so clearly put forward by your contributor Mr. Badenoch (Nov. 3, p. 601).—I am, etc.,

Anatomical Department,
St. Thomas's Hospital, S.E.1.

R. WHEELER HAINES.

Routine Treatment of Malaria with Intravenous Quinine

SIR,—During the Japanese occupation of Hong Kong, when forced by economic reasons and shortage of drugs, the routine treatment of malaria was with intravenous quinine. It has been shown in a series of 100 patients that the slow injection of quinine dihydrochloride by this route has great advantages, for it is absolutely painless and does not lead to necrosis of the muscular tissue of the buttocks as intramuscular injections do even under sterile conditions. The plasmodia in the blood stream disappear rapidly, the fever drops in one to two hours after the injection, and the temperature usually reaches normal much more quickly than after intramuscular application. I have used intravenous quinine dihydrochloride not on specially selected material, but on the undernourished population of Hong Kong under Japanese rule. The dosage was 0.25 to 0.5 gramme in 1 c.cm. distilled water. I did not use glucose because it was too expensive. The injection took two minutes, and aspirated blood was constantly mixed with the solution of quinine. The temperature in 95 cases fell to normal after one injection only, while in 5 cases (subtertian malaria) a second injection was necessary five hours after the first. Racially the 100 patients were 10 Europeans, 36 Chinese, 54 Indians. The last group were watchmen or prisoners of war in a very bad physical condition. The reactions of the patients are given below:

Reaction	Objective and Subjective Signs	Number of Cases	Kind of Malaria
None		80	73 tertian 4 quartan 3 subtertian
Slight	Feeling of heat in chest and of slight pressure on the heart	15	12 " " " " " "
Moderate	Dizziness, nystagmus, nausea, burning sensation in chest	3	3 tertian 2 mixed 1 subtertian
Severe	Severe dizziness, nausea, tachycardia, extrasystole	2	2 " "

No patient collapsed and no death was reported. I conclude that it is better to use quinine dihydrochloride intravenously than intramuscularly, as this route is safe and quick and all the quinine administered enters the blood stream.—I am, etc.,

Hong Kong.

W. WINTERSTEIN.

National Research into Tuberculosis

SIR,—The suggestion put forward by Dr. George Luntz in his letter (Dec. 1, p. 781) is not only very timely but in a sense rather overdue. I have now been connected for about three years with one of the largest sanatoria and E.M.S. hospitals in the country. The difference between the two types of patients (tuberculous and E.M.S.) is so tragically glaring that it cannot be missed. The age groups of Service tuberculous cases and Service casualties from all other causes are broadly the same. But whereas a patient in the latter group, with the help of sulphonamides, penicillin, and plastic and modern orthopaedic surgery, stands a very fair chance of getting over his disabilities, one in the other group (tuberculous), in spite of all modern medical and surgical treatment, stands with the sword of Damocles perpetually hanging over his head.

Tuberculosis is a disease by itself. Its insidious onset often makes it very difficult to diagnose in time. Its infectivity, which is a very real source of danger to the last day of the patient's life and whose main victim is the youth of the nation, makes it a national problem of very great importance. Further, due to its chronicity, it is not amenable to short-time "isolation policy" as is possible with smallpox and other similar infectious diseases. There is no disease in the country which can compare with tuberculosis in all its implications and tragedies, and its indeed is a disease which does not die with the patient.

In modern times, when scientific research has given us the sulphonamides, penicillin, radar, and the atomic bomb, is it so much to hope that concentrated research as suggested by Dr. Luntz will find an answer to this problem, which is, from both the individual and the national aspect, of priority importance.—I am, etc.,

London, W.2.

H. C. MURPHY

Questionnaires, Past and Future

SIR,—The blast of war blows in our ears. . . . The game of "foot ball." A week or two ago the headlines of a Sunday newspaper told us that all voluntary hospitals are to be taken over by the Government. When questions were raised the statement was not withdrawn but reaffirmed in the next issue. Then follows Mr. Aneurin Bevan's statement in the House of Commons, on Dec. 6, 1945, on: (a) Abolition of the sale and purchase of practices; (b) "proper distribution" of doctors (i.e., direction); (c) "appropriate measure of compensation"; (d) "great satisfaction with which this statement will be received by most doctors." This menacing pronouncement threatens the very foundations of our professional life, is in direct conflict with our oft-repeated principles, and will inevitably lead to a whole-time salaried State medical service. Personally, I believe compensation will take the form of a pension which will have the effect of strengthening Government control over us; in other words, there will be no compensation unless we enter the service.

I am surprised to read in the *Journal* of Dec. 15 (p. 851) that there still persists a naive belief in the B.M.A.'s Questionnaire issued about two years ago, and am disturbed to think that our policy may be based unduly on its results. The Questionnaire was a blunder, inasmuch as (by the ambiguous manner in which it was framed) the results could not possibly be a true reflection of the views of the profession. And even if this is not admitted, I contend that the Questionnaire is now out of date. We now see the issues at stake more clearly, and have more considered views. And we have a Government in power of whose policy we are in little doubt. I earnestly suggest, therefore, that the time is very ripe for the B.M.A. to issue a short Questionnaire based on fundamental issues—direct unequivocal questions that can easily be answered "Yes" or "No." For your consideration and that of the profession in general I suggest the following:

- (1) Are you in favour of a whole-time State salaried service?
- (2) Do you favour abolition of the sale and purchase of practices?
- (3) Do you consider it essential for the welfare and independence of the profession and in the public interest that private practice should continue?
- (4) Are you in favour of the compulsory inclusion of 100% of the population in any service?
- (5) Are you opposed to any form of local government control of the profession?
- (6) Are you opposed to any form of direction of doctors?
- (7) Should the voluntary hospital system be preserved?

Some time ago we here in Perth sent out a similar questionnaire to 123 doctors in this area, with most satisfactory results. Suffice it to say that if the replies are a reflection of the views of individual doctors throughout the country then the questionnaires I suggest would greatly strengthen the hands of our negotiators. 'Tis a consummation devoutly to be wished.—I am, etc.,

ROBERT RITCHIE.

Perth, Scotland.

D. P. Barr and E. Shore (*Ann. intern. Med.*, 1945, 23, 754) treated 100 cases of Graves's disease with thiouracil and obtained remissions in 87. Mild and many recurrent cases were easily brought under control. On the other hand large nodular goitres responded less readily.

Obituary

SIR ARTHUR BALL, Bt., M.D., M.Ch.

We regret to announce that Sir Arthur Ball, Regius Professor of Surgery in the University of Dublin for the past twelve years, died suddenly at Carrickmines, Co. Dublin, on Dec. 21.

Charles Arthur Kinahan Ball, born on March 29, 1877, was the eldest son of Sir Charles Bent Ball, first baronet, honorary surgeon in Ireland to King Edward VII and King George V; nephew of Sir Robert Stawell Ball, F.R.S., the astronomer whose writings and popular lectures reached a very wide audience; and grandson of Robert Ball, LL.D., the well-known Dublin naturalist who came of an old Devon family which settled in Ireland in 1651. Arthur Ball graduated B.A. from Trinity College, Dublin, in 1898, with honours in natural science, took the M.B., B.Ch., and B.A.O. degrees in 1900, and the M.D. in 1902, in which year he won the surgical travelling prize. He was elected F.R.C.S.I. in 1905 and received the M.Ch. degree of Dublin University thirty years later. After a demonstratorship of anatomy at Trinity College and post-graduate study in Berne and Baltimore he became house-surgeon and later assistant surgeon to Sir Patrick Dun's Hospital, of which his father was an ornament. He was also elected surgeon to Monkstown Hospital and a number of other institutions in and around Dublin, and lectured on operative surgery at Trinity College and examined for the Royal College of Surgeons in Ireland. He succeeded to the baronetcy on March 17, 1916, and in 1933 was appointed Regius Professor of Surgery, as his father had been many years earlier.

Sir Arthur Ball joined the British Medical Association in 1902 and held office as secretary of the Section of Surgery at the Birmingham Annual Meeting in 1911. He was a member of the Council of the Royal Zoological Society of Ireland and past-president of the Dublin University Biological Association, thus continuing the active interest taken by his grandfather in each of those scientific bodies. He published a number of papers on urological subjects in this and other journals, and his presidential address to the Section of Surgery of the Royal Academy of Medicine in Ireland on "Progress of Renal Surgery" appeared in the *Dublin Journal of Medical Science* in 1912. He married in 1907, but had no child, and his brother, Nigel Gresley Ball, Sc.D., late professor of botany at University College, Colombo, succeeds to the title.

SIR FARQUHAR BUZZARD

DR. GORDON M. HOLMES writes:

Apart from his work while he presided over the medical faculty at Oxford and his services to the Nuffield Trust, particularly in the reorganization of hospital facilities and teaching in provincial centres, in which his exceptional organizing ability was recognized, Buzzard occupied a prominent place in contemporary medicine.

Even in the early years of the century when he held the post of pathologist at the National Hospital, Queen Square, his clinical ability was rated so highly that his help and advice on difficult problems which arose in the wards of the hospital were regularly sought by his junior colleagues. As the years passed and his experience grew, his opinion and judgment came to be more widely appreciated in other branches of clinical medicine as well as in neurology. He possessed an exceptionally developed clinical instinct, and an ability to take into account and weigh up every side of each problem that confronted him, which was supplemented by an adequate knowledge of the anatomy and pathology of the nervous system. Although his name is not associated with any important discovery or notable addition to knowledge, he made several valuable contributions to neurology, as the clinical differentiation and morbid anatomy of subacute combined degeneration of the spinal cord, in which he was associated with Batten and Collier.

His deliberate manner and his slow and cautious expression of opinion may have diminished his popularity as a teacher, but his classes and demonstrations both at St. Thomas's Hospital and at the National Hospital were highly appreciated by more

advanced and thoughtful students, and particularly by post-graduates.

Buzzard's friends and colleagues will, however, ever remember him for his personal qualities: his sincerity and obvious honesty, his acute sympathy and his willingness to help in difficulties of any nature, his wide interests, and the cheerfulness he brought to any company he entered.

The following well-known medical men have recently died abroad: Dr. GASTON MILIAN, the eminent French dermatologist; Dr. WALTER BIGLEN, a St. Gallen gynaecologist and an authority on Paracelsus; Dr. JEAN TROISIER, professor at the Paris faculty of medicine and Institut Pasteur and an authority on tuberculosis and cancer; Dr. FRITZ RUTISHAUSER, the first Swiss psychiatrist for abnormal children and young persons, aged 70; Dr. W. W. HERRICK, professor of clinical medicine in the College of Physicians and Surgeons at Columbia University and president of the New York Academy of Medicine; Dr. JUAN SANCHEZ COVISA, emeritus professor of dermatology in the Madrid faculty of medicine.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Applications for the John Lucas Walker Studentship, the holder of which must devote himself to research in pathology, are invited, and should be sent, accompanied by testimonials, references, and copies of papers containing published work, before April 20, 1946, to Prof. H. R. Dean, Department of Pathology, University of Cambridge, to whom also applications for further information regarding the studentship may be addressed. Persons of either sex may be candidates. The Studentship is tenable for such period and is of such annual value not exceeding £500 as the Professor of Pathology, with the approval of the Managers, may determine.

At a Congregation held on Dec. 15 the following medical degrees were conferred, all by proxy except where indicated by an asterisk:

M.D.—A. H. Masina, *W. P. Purvis.
M.B., B.Chir.—W. S. R. Fenton, D. A. Bailey.
B.Chir.—J. F. Paterson.

The examination for the degree of M.Chir. will be held on Feb. 19, 20, 22, and 23.

The following candidates have been approved at the examination indicated:

FINAL M.B.—Part II (*Principles and Practice of Physic, Pathology, and Pharmacology*): R. C. Allison, A. C. Arthur, J. C. Bayliss, J. P. M. Bensted, J. E. Blundell, F. J. Conway, D. G. Davidson, W. H. Davies, E. W. Deane, A. M. Dorey, N. K. Dryden, A. L. T. Easton, J. O. P. Edgcombe, E. Ellis, R. H. Ellis, T. A. Evershed, A. E. Flatt, A. L. Furniss, D. A. G. Galton, E. B. Geihen Smith, J. H. Gough, R. N. Grabowsky-Atherstone, B. A. J. C. Gregory, D. Hamilton, P. H. Hewitt, W. A. A. Hodges, E. M. James, J. Jordan, M. C. Joseph, P. B. Kunkler, P. K. Ledger, A. H. Littlewood, P. N. Magee, J. B. Metcalfe, R. I. Milne, P. D. Mort, G. S. Ostlere, P. P. Philip, J. E. Pitts, B. R. Pollard, C. W. A. Pullan, B. O. Reed, J. T. Rowling, C. C. D. Shute, I. B. Smith, R. H. Thomlinson, P. H. Walker, M. W. P. Ward, P. Watson, R. H. Wilkinson, C. J. Wilson. *Women*: K. A. C. Bowen, M. A. Brown, M. C. Myddelton.

UNIVERSITY OF LONDON

Ralph Ford Tredre, M.D., D.P.H., D.T.M.&H., has been appointed Assistant Director of the Ross Institute of Tropical Hygiene, which is incorporated in the London School of Hygiene and Tropical Medicine. The appointment dates from October last.

Aubrey Lewis, M.D., F.R.C.P., has been appointed to the university chair of psychiatry tenable at the Maudsley Hospital, where he has been clinical director since 1936.

The title of professor of applied physiology in the University has been conferred on Guy Pascoe Crowden, D.Sc., M.R.C.P., in respect of the post now held by him at the London School of Hygiene and Tropical Medicine.

J. H. Birkinshaw, D.Sc., has been appointed to the university readership in biochemistry tenable at the London School of Hygiene and Tropical Medicine.

UNIVERSITY COLLEGE HOSPITAL MEDICAL SCHOOL

The Medical Research Council and University College Hospital Medical School have jointly appointed Edward Eric Pochin, M.B., B.Chir., M.R.C.P., to be Director of the Department of Clinical Research, in place of the late Sir Thomas Lewis, as from Jan. 1. Dr. Pochin has also been appointed an honorary physician to University College Hospital.

UNIVERSITY OF BRISTOL

Robert Milnes Walker, M.S., F.R.C.S., has been appointed to the newly established Chair of Surgery in the University.

UNIVERSITY OF LIVERPOOL

The following candidates have been approved at the examinations indicated:

M.D.—J. R. Hughes, C. McGibbon, H. Reid.
M.B., Ch.B.—*† R. G. Thomas, *† L. F. Tinckler, *† Esmé M. Wren. *Part III*: Audrey M. Ashcroft, N. L. Bailey, † K. Baker, S. Beacon, D. T. Binas, R. Brearley, P. M. Bretland, Cécile N. Broster, J. H. E. Carmichael, Helen A. Cawson, A. D. Charnley, M. H. Clark, N. Coulshed, S. Croft, Pauline M. Dean, M. M. I. el Haddad, R. Ellam, H. C. Graham, E. A. Harris, F. G. Ince, R. V. Kennon, Barbara M. Killick, T. S. Law, Jean Learoyd, A. C. Levinson, T. R. Littler, J. A. O'Garra, A. E. Pritchard, Rachel M. Rawcliffe, G. P. Reed, H. Roberts, W. G. Roberts, P. W. Robertson, Olive R. Rodgers, L. Rosenbloom, H. H. Slack, Helen M. Taylor, L. Temkin, J. Ward, Joyce Watson, N. P. Watson, W. F. Wille, Aline N. Wynroe. *Passed in Separate Subjects*: Ailsa M. Heath (Medicine and Obstetrics and Gynaecology), Maureen M. Hoey (Surgery and Obstetrics and Gynaecology), D. T. L. Hughes (Medicine and Surgery), H. S. Levy (Medicine and Surgery), F. W. Sheffield (Medicine and Surgery).

* With second-class honours. † Distinction in surgery. ‡ Distinction in obstetrics and gynaecology.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

Dr. Hugh Edward Magee will deliver the Milroy Lectures on Tuesday, Feb. 12, and Thursday, Feb. 14, at 5 p.m. at the College, Pall Mall East. His subject is "Application of Nutrition to Public Health—Some Lessons of the War." Tea will be served before the lecture.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Sir William H. Collins and Sir Henry Dale, O.M., G.B.E., F.R.S., have been elected Honorary Fellows of the Royal College of Surgeons. Sir William Collins is one of the greatest benefactors in the history of the College, having endowed professorships of anatomy and pathology in recent years. Sir Henry Dale, when President of the Royal Society, was a Trustee of the Hunterian Collection and has also been associated with the College through his membership of the Council of the Imperial Cancer Research Fund.

At an ordinary meeting of the Council of the College, held on Dec. 13, Sir Alfred Webb-Johnson, Bt., President, in the chair, diplomas of Fellowship were granted to the following successful candidates:

R. H. Gardiner, F. T. Moore, K. F. Hulbert, H. H. Barst, F. D. Hindmarsh, J. E. Malcolm, D. Wynn-Williams, S. Muntarbhorn, R. A. Gill, V. G. Patel, P. W. Brand, D. R. Barnes, G. L. W. Bonney, J. Zimmerman, P. G. Somerville, R. E. Waterston, I. D. Gebbie, W. H. Rothwell, R. S. Hooper, E. E. O'Malley, W. Hawksworth, L. Gillis, M. Kaye, J. W. Spence, G. R. Nicks, W. K. Yeates, G. Harrison, V. G. Griffiths.

A diploma of membership was granted to Janet Gordon (King's College, London).

Diplomas in Anaesthetics were granted, jointly with the Royal College of Physicians of London, to the following successful candidates:

Valerie M. Adamson, C. R. G. Barrington, C. H. D. Bartley, F. H. Blackburn, R. I. Bodman, G. Bourne, A. Brown, W. M. Brown, J. D. Buxton, E. S. Curtiss, S. G. de Clive-Lowe, I. A. Donaldson, C. Frost, P. R. Gavin, H. S. H. Gilmer, E. G. Godwin, J. M. Graham, J. Greenhalgh, The Hon. E. B. Hacking, L. A. I. Hamilton, Beryl L. Harrison, Monica L. Hawkins, A. N. Hobbs, M. Holborow, J. Howell, Margaret M. G. Joat, G. T. Johnson, G. S. A. Knowles, H. T. Knowles, O. V. S. Kok, Gwenda M. Lewis, B. R. Little, A. M. MacKay, J. M. MacKinnon, F. G. Mackintosh, J. A. McNab, Elizabeth H. Milne, D. A. Naismith, Olive I. Nicholson, P. T. Northover, J. R. O'Dowd, M. B. O'Neill, M. W. Li. Owen J. A. Pearl, P. B. Percheson, E. H. D. Phillips, R. I. Probert, Barbara C. Roberts, A. H. Tin, Daphne V. Veale, G. L. Were, R. U. Whitney, G. M. Wyant, J. B. Wyman.

Messages of greeting from the College were recently conveyed to the Royal Australasian College of Surgeons by two members of the Council now in Australia—Surg. Rear-Adm. G. Gordon-Taylor and Surg. Capt. Lambert Rogers. Copies of the messages and the reply from the President of the Royal Australasian College of Surgeons, Mr. H. R. G. Poate, were before the Council.

St. James's Hospital, Leeds, was recognized for the resident surgical post required of candidates for the Final Fellowship examination in respect of the posts of resident surgical officer and first house-surgeon.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the Royal College of Surgeons of Edinburgh held on Dec. 19, with Mr. Jas. M. Graham, President, in the chair, the following candidates, having passed the requisite examinations, were admitted Fellows:

D. W. A. Degazon, W. H. Fahrni, J. F. M. Fraw, E. Garland-Collins, N. O. K. Gifford, R. Hodgkinson, W. Irving, M. J. Kelleher, J. H. Kirkham, J. R. F. Mills, R. C. Rider, I. C. Simpson, F. Smith, W. M. Toone.

Dr. A. B. Alexander has been notified that the Fellowship of the American College of Surgeons (F.A.C.S.) was formally conferred upon him, *in absentia*, in Chicago on Nov. 30, 1945.

The Services

Air Vice-Marshal T. J. Kelly, C.B.L. M.C., has been appointed an Honorary Surgeon to the King in succession to Air Vice-Marshal F. C. Cowan, C.B., who has vacated the appointment on retirement from the R.A.F.

Major (Acting) B. H. Price, R.A.M.C., has been appointed M.B.E. (Military Division) in recognition of gallant and distinguished services in the field.

Surg. Cmdr. J. F. Heggie, R.N.V.R., has been awarded the R.N.V.R. Officers' Decoration.

The following appointments and mentions in dispatches have been announced in recognition of gallant and distinguished services while in the ranks of war:

O.B.L. (Military Division)—Lieut.-Col. D. A. McM. Crawford, J. T. Hankey, and T. H. Wilson; Lieut.-Cols. (Temp.) J. C. MacLay, J. C. T. D., and D. H. Thompson; Major V. R. Henderson, R.A.M.C.

M.B.E. (Military Division)—Major J. G. Lawson, Majors (Temp.) S. W. Barber, G. MacN. R. Duffus, R. Harvey, C. W. Forncastle, P. D. C. Kimmont, L. W. Lauste, J. B. Sherran, W. S. Jakes, and A. W. Woolley; Capt. P. T. Cooper, W. O. James, L. W. MacMillan, W. M. Nichols, I. F. Rose, and D. Taverner, R.A.M.C.

Mentioned in Dispatches—Lieut.-Col. (Acting) A. G. D. Whyte, I.B.E. Major B. B. Hosford; Majors (Temp.) W. M. Davidson, L. R. Gordon, M.C., W. R. Hunter, C. W. A. Kimbell, J. Parkes, J. Smith, and A. McL. W. Thomson; Capt. J. H. Annan, M.B.E.; Lieut. Bonham Carter, A. M. Boyd, J. C. Cameron, E. F. M. Caraher, E. S. Carmichael, G. D. Cribb, A. Crook, G. I. Davidson, J. Forrest-Hay, W. K. Frewen, J. H. Gibson, S. S. B. Gilder, R. W. Henderson, D. R. Holden, W. S. Holden, D. G. Howatson, W. I. S. Ludleston, C. W. Hille, J. A. James, G. S. A. Knowles, D. W.acey, F. B. Lake, N. R. Lansdell, R. P. Lawson, M.C., W. Lumsden, R. J. MacDonald, L. MacLean, A. Macnab, A. Milchides, N. E. Fonteuus, A. F. Murray, G. F. R. Parker, R. Pollock, D. H. andall, R. Robertson, R. L. Sanderson, I. Schrire, C. A. Simmons, F. Smith, I. O. B. Spencer, I. McD. G. Stewart, A. C. P. D. homson, M.C., C. E. C. Wells, and R. M. Wiltshire; Lieut. J. outlieb, R.A.M.C.

Medical Notes in Parliament

During the autumn sittings the Parliamentary Medical Group under the chairmanship of Dr. Haden Guest has concerned itself with a number of matters connected with demobilization. These included the release of requisitioned accommodation in medical schools, the release of medical teachers from the forces, and the acceleration of the demobilization of medical actionnaires. After the House of Commons resumes on January 1 the committee will consider the arrangements for the care of aged in sickness and health.

The Royal Assent was given on Dec. 20 to the Finance (No. 2) Act, the Public Health (Scotland) Act, and the Workmen's Compensation (Pneumoconiosis) Act.

Tuberculosis Contracted by Nurses

While the National Insurance (Industrial Injuries) Bill was for a Standing Committee of the House of Commons on Dec. 4, Mrs. BRADDOCK moved to provide that in the case of nurses contracting tuberculosis during nursing employment, or within six months afterwards, the disease should be deemed to arise from the carrying out of such nursing employment. She said that in the Civil Nursing Reserve nurses were entitled to a special pension when they had contracted tuberculosis or any other infectious disease.

The CHAIRMAN of the COMMITTEE suggested that this amendment could be discussed together with a similar one relating to workers in the cotton textile industry who contracted epithelioma or spinners' cancer.

Mr. JAMES GRIFFITHS, replying for the Government, said that spinners' cancer would be covered by the new Bill and he would have jurisdiction to prescribe the time limit. He was considering the desirability of extending this beyond 12 months. He asked Mrs. Braddock to withdraw her amendment because he did not wish the clause to mention the people to whom it applied. It was a general clause enabling him to prescribe any injury or a disease. That was being considered for the nurses' consultation with the Ministry of Health and the Department of Health for Scotland. He hoped to arrive at a decision before long.

Penicillin for the Public

Mr. Wilmot (Minister of Supply) was asked on Dec. 17 whether he would arrange for penicillin to be sold to the public in tablet form "to avoid the hardship, inconvenience, and expense of having to go to hospitals, clinics, or surgeries for injections." Mr. WILMOT replied that treatment with penicillin otherwise than by injection could not at present be recommended for general use. Extensive research was being carried out. As soon as a suitable technique was established, steps would be taken to make the necessary preparations of penicillin available in accordance with the recommendations of the medical authorities of the Ministry of Health.

German Scientists for Britain

Sir STAFFORD CRIPPS stated on Dec. 19 that it was proposed to recruit, on the recommendations of the responsible Department, a strictly limited number of German scientists and technicians of the highest grade for service in this country, in the first instance for a period of six months. In general these experts would work in Government establishments, or for research associations sponsored by the Department of Scientific and Industrial Research.

Beds for Tuberculosis

Mr. BEVAN told Mr. Pritt on Dec. 20 that the number of persons awaiting sanatorium treatment for tuberculosis was about 5,000 and the number of beds normally available, but at present out of use owing to shortage of staff, was about 3,000. All possible measures to remedy the shortage of staff were being taken by his officers and those of the Minister of Labour. The importation of displaced persons for this work was under consideration, but was not without difficulty.

Mr. BUCHANAN stated that in Scotland the total number of beds available in sanatoria for tuberculous patients was approximately 6,700, but it was estimated that 500 of them could not be used through shortage of nursing staff. At Sept. 30 the number of persons on the Scottish local authorities' waiting lists was 1,703, including fully 1,000 from Glasgow.

New National Insurance Bill

Mr. JAMES GRIFFITHS presented on Dec. 20 the National Insurance Bill to establish an extended system of national insurance, providing payments by way of unemployment benefit, sickness benefit, maternity benefit, retirement pensions, widow's benefit, guardians' allowance, and death grant, to repeal or amend existing enactments relating to national health insurance and other schemes, and to provide for the making of payments towards the cost of a national health service. Answering questions about this Bill, Mr. Griffiths said he hoped it would be available before the House resumed in January, but owing to the complexities of the task it might not be possible to have the Bill printed until shortly after the House resumed its sitting on Jan. 22. He believed his would not prejudice the Government's intention to get the Bill on the Statute Book before the summer recess.

Manufacture of D.D.T.

Replying on Dec. 20 to Sir Patrick Hannon, Sir STAFFORD CRIPPS said the factories where D.D.T. was manufactured during the war were still in operation. One firm began commercial distribution of its product last September. It was proposed to give the other producers an early opportunity of making D.D.T. for their own account, subject to provision for current and future requirements of the fighting Services and other Government demands.

Permanent Medical Staff of R.A.F.

Mr. STRACHEY stated on Dec. 20 that 139 medical officers held permanent commissions in the R.A.F. In addition 56 officers had recently been selected for permanent commissions. Thirty-five officers had been offered extensions for four years. Thus far five had accepted. In the second half of 1945, 880 medical officers would have been released and recruitment during the same period would have been nil.

Hospital Survey of West Midlands

The report for the West Midland area on the hospital services in the regional district included in the survey was issued on Oct. 24 for consideration by those concerned, locally and centrally, in the future planning and organization of hospital services. Mr. BEVAN said on Dec. 20 that action on the recommendations made would be premature in advance of the organization and development of the health services as a whole.

Food of Displaced Persons—Mr. J. HYNDS, in a statement on Dec. 20, said that in the British zone in Germany displaced persons

had absolute priority over the German population in regard to food. A minimum ration scale of 2,000 calories a day was prescribed with additions for special categories. This was much in excess of what was being received by the Germans. At one assembly centre near Belsen, where a large number of displaced persons were accommodated, the hospital was administered by U.N.R.R.A. There was an adequate supply of medicine and the hospital was well fitted and well run. Some German doctors and nurses worked there under the direction of U.N.R.R.A. doctors. The food scale in force provided 2,913 calories per day for nursing and expectant mothers.

Superannuation of Asylum Officers.—Asked by Mr. Rhys Davies on Dec. 20 to introduce a short Bill to amend the Asylums Officers Superannuation Act, 1909, so as to remove the anomaly whereby an employee was not allowed the return of his contributions on voluntary resignation when not guilty of misconduct, Mr. BEVAN promised to consider this suggestion with others made from time to time for the amendment of the law relating to the superannuation of local government and other officers. He added that he held out no hope of early legislation on these matters.

Priority Milk.—About 600,000 adult consumers, other than expectant mothers and mothers of infants, receive priority milk. The Ministry of Food is inquiring whether any tightening of the procedure is needed. Sir Ben Smith is advised that there are no nutritional grounds for allowing extra milk to old-age pensioners.

Shortage of Medicine Bottles.—Sir E. GRAHAM-LITTLE asked on Dec. 19 about the shortage of medicine bottles. Sir STAFFORD CRIPPS said glass bottles were in short supply, but priority was given to bottles required for food, drink, and medicines. He was considering with Mr. Isaacs what further steps could be taken to increase the workers in the industry.

Notes in Brief

The Interdepartmental Committee on Dentistry has submitted its final report, which will be published as a Command Paper.

An allocation of sugar is to be made by the Ministry of Food to a firm manufacturing homoeopathic medicines for export.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the chief features of the returns were large increases in acute pneumonia (225 more cases) and dysentery (71 more cases). The only other variations of note were decreases in whooping-cough and scarlet fever (30 and 26 fewer cases). Only small changes occurred in the local incidence of scarlet fever and whooping-cough.

Measles showed an increase in Suffolk (43) and a decrease in Lancashire (46).

Diphtheria cases increased in Yorks West Riding (17) and Suffolk (12), and decreased in Durham (17) and Lancashire (14).

Dysentery was reported from Hertfordshire, Hatfield R.D., where there was a large outbreak involving 90 persons. Other large returns were Lancashire 51, London 44, Yorks West Riding 20, Essex 13, Warwickshire 10.

In *Scotland* a large fall (63) was recorded in the incidence of pneumonia. There were 28 fewer cases of diphtheria, while scarlet fever rose by 27. The fall in diphtheria was mainly due to Glasgow, where the cases fell from 84 to 62.

In *Eire* the only variations in the trends of infectious diseases were a fall in measles (21) and an increase in whooping-cough (17). In Dublin C.B. 33 further cases of diarrhoea and enteritis were notified.

Quarterly Returns for Northern Ireland

The birth rate during the September quarter was 21.8 per 1,000, compared with 22.5 for the average of the five preceding third quarters. Infant mortality was 53 per 1,000 registered births—15 below the average for the five preceding September quarters. Maternal mortality was 3.2 per 1,000 births, which is the same rate as the five-years average. The general death rate was 10.1 per 1,000, which was 1.1 below the five-years average. Deaths from pulmonary tuberculosis were 171, and from other forms of tuberculosis 50, these totals being 42 and 19, respectively, below the average of the five preceding third quarters. Deaths from epidemic diseases included 97 from diarrhoea and enteritis under 2 years of age, 14 from whooping-cough, 10 from influenza, and 7 from diphtheria.

Week Ending December 22

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,718, whooping-cough 1,100, diphtheria 569, measles 623, acute pneumonia 1,166, cerebrospinal fever 43, acute poliomyelitis 23, dysentery 230, paratyphoid 4, typhoid 5.

INFECTIOUS DISEASES AND VITAL STATISTICS

No 50

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 15

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire. (e) Northern Ireland

Figures of Births and Deaths, and of Deaths recorded under each Infectious disease are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland

A dash — denotes no cases; a blank space denotes disease not notifiable or return available

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to movements of population, birth and death rates for Northern Ireland are still not available.

Medical News

Authors of original articles and medical memoranda published in this *Journal* will from now onwards be entitled to 50 free reprints, and will be charged only for the number ordered in excess of this.

The twenty-ninth course of instruction for a Diploma in Psychological Medicine will open at the Maudsley Hospital Medical School, Denmark Hill, S.E.5, on Jan. 7, and will comprise a large number of lectures and clinical demonstrations. All inquiries about the course should be addressed to Dr W. W. Kay, acting honorary director of the Maudsley Hospital Medical School, Central Pathological Laboratory, at West Park Hospital, Epsom, Surrey (telephone: Epsom 1408). Clinical instruction in psychiatry will be arranged, for students who desire to satisfy the requirements of the various examining bodies in respect of clinical experience of mental disorders for a D.P.M.

Prof. Willem Noordend, Hon. F.R.C.S., who holds the chair of surgery in the University of Amsterdam, will deliver the Mounihan Lecture, on the choice of oblique and transverse incisions in abdominal surgery, at the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., on Wednesday, Jan. 9, at 5 p.m.

The Pharmaceutical Society of Great Britain has arranged a meeting at 17, Bloomsbury Square, London, W.C., on Thursday, Jan. 10, at 7 p.m., when the Harrison Memorial Medal will be presented to Mr. Reginald Robert Bennett, B.Sc., F.R.I.C. After the ceremony Mr. Bennett will give an address in which he will deal with pharmacopoeia revision and will review historically the part which pharmacists have played in this work since the Medical Act of 1858 vested in the General Medical Council responsibility for producing and publishing the *British Pharmacopoeia*.

A joint meeting of the Microbiological Part of the Food Group of the Society of Chemical Industry with the Society for Applied Bacteriology will be held on Jan. 9, at 2.15 p.m., in the rooms of the Chemical Society, Burlington House, Piccadilly, W., when papers will be read on heat-resistance of micro-organisms, on some problems in the bacteriology of rivers, and on mould growth on leather. Members may introduce friends in person. The office of the Society of Chemical Industry is at 56, Victoria Street, S.W.1.

The European Association of Clinical Pathologists will hold its annual general meeting at Glaxo Laboratories Ltd., Greenford, Middlesex, on Saturday, Jan. 12, at 10 a.m.

A meeting of the Eugenics Society will be held in the rooms of the Royal Society, Burlington House, Piccadilly, W., on Tuesday, Jan. 15, at 5.30 p.m., when Dr. Elhat Slater will discuss "An Intercourse into Assortative Mating," and Mrs. Moya Woodside will speak on "Courtship and Mating in an Urban Community." All interested in the subjects are invited to attend.

The Medical Society of London has arranged the following course of lectures to be given at 11 Chandos Street by Fellows of the society to any demobilized medical officers who may wish to attend. Each lecture will begin at 5.10 p.m.: Tuesday, Jan. 15, "The Acute Abdomen," Mr. V. Zachary Cope; Friday, Jan. 18, "Surgical Diseases of the Bladder," Mr. E. W. Riches; Tuesday, Jan. 22, "Infections of the Hand," Mr. R. M. Handfield-Jones; Friday, Jan. 25, "Gastro-enteritis of Children," Dr. C. F. Harns; Tuesday, Jan. 29, "Oesophagus," Prof. G. Grev Turner; Friday, Feb. 1, "Diagnosis and Treatment of Diabetes," Dr. Wilfred Oakley; Tuesday, Feb. 5, "Thyrotoxicosis," Dr. T. Jenner Hoskin, F.R.C.P.; Friday, Feb. 8, "Toxaemia of Pregnancy," Mr. Aleck Bourne; Tuesday, Feb. 12, "Disorders of Menstruation," Mr. A. C. Palmer; Friday, Feb. 15, "Indications for Chest Surgery," Mr. A. Tudor Edwards; Tuesday, Feb. 19, "Ophthalmic Emergencies," Mr. F. A. Williamson-Noble; Friday, Feb. 22, "Otitis Media," Mr. W. M. Mollison; Tuesday, Feb. 26, "Brachial and Scapular Pain," Dr. Anthony Feilding; Friday, March 1, "The Pneumonias," Dr. Geoffrey Marshall; Tuesday, March 5, "Nephritis and Hypertension," Dr. Horace Evans.

The Ministry of Health announces that the Rushcliffe Committee has decided that the new scales of salaries for ward sisters, staff nurses, and assistant nurses comes into operation from Jan. 1, 1946. The estimated cost of the increases is roughly £500,000 a year to begin with, rising to £1,000,000 a year from April 1, 1947. The Rushcliffe Committee has also agreed that extra allowances should be paid for continuous service in pulmonary tuberculosis hospitals. Qualifying service for these allowances will be reckoned from Jan. 1. In informing local authorities and voluntary hospitals of these recommendations, the Minister of Health "warmly welcomes" them. He states that half the additional cost will be met by them. He states that half the additional cost will be met by them. He states that half the additional cost will be met by them. Exchequer grant (pending settlement of the post-war health services) on condition that employing authorities implement the Rushcliffe Committee's salary recommendations in full.

Dr. E. D. Pridie, C.M.G., D.S.O., O.B.E., has been appointed health expert at His Majesty's Embassy, Cairo.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to The Editor, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1. Telephone: EUSTON 2111. Telegrams: *Articulate, Medico, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, as soon as possible. Authors overseas should indicate on MSS. if reprints are required, as proof are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). Telephone: EUSTON 2111. Telegrams: *Articulate, Medico, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association, Telephone: EUSTON 2111. Telegrams: *Medico, London*.

B.M.A. Scottish Office: 7, Drumchapel Gardens, Edinb.-22.

ANY QUESTIONS?

Age of Descent of Testes

Q.—What is the latest age at which testes have been known to descend into the scrotum (1) without special therapy, and (2) with special endocrine therapy?

A.—In the case of patients with retained testes who are otherwise normal and show no endocrine stigmata, if the testis does not descend before puberty (12 to 14 years of age) it is unlikely to do so, either spontaneously or with endocrine therapy, at a later date. Such a testis is probably ectopic. Where, however, an undescended testis is part of an endocrine syndrome—e.g., Fröhlich's syndrome—gonadotrophic hormone may produce descent in adolescence or adult life, but spontaneous descent is less likely. In the case of an ectopic testis surgery will be required.

Van Gierke's Disease

Q.—What treatment would you recommend for van Gierke's disease in a patient aged 12?

A.—The disease in question appears to be an inborn error of glycogen metabolism, this storage product is not mobilized readily, to keep up the blood-sugar demand, and therefore accumulates in the tissues, especially, of course, the liver. Little has been added to the knowledge of the exact mechanism of fault, since the original description. No treatment appears to be of any avail, but in view of the effect of adrenaline in mobilizing liver glycogen in normal subjects it might be worth trying regular small doses of epinephrine.

Tests for Addison's Disease

Q.—Might insulin sensitivity tests be useful in the early diagnosis of Addison's disease, as in Simmonds's disease? Hypoglycaemia is known to be a feature of exacerbations, and the adrenal is known to produce an "anti-insulin" substance.

A.—Insulin tests might be useful, but normal findings in Addison's disease. This is because (1) the response to insulin may be normal in the early phases of Addison's disease, and sometimes even in the later phases; and (2) because the diabetogenic or anti-insulin function of the pituitary gland has been shown to operate even in the absence of the adrenal glands, although part of this action may be indirectly through the adrenal glands. The writer has carried out insulin-sensitivity tests in Addison's disease, and the results, broadly speaking, appear to be half-way between the normal response and that obtained in Simmonds's disease. In his opinion, there are more useful tests in the diagnosis of Addison's disease, of which the most valuable is that of Kepler (F. J. Robinson, M. H. Power, and E. J. Kepler, *Proc. Mayo Clin.*, 1941, 16, 577), which measures water and chloride metabolism and excretion.

Qualifications for Assistant M.O.H.

Q.—What are the legal and technical qualifications necessary for an assistant to a medical officer of health of a population of 40,000 or over, or, in the case of Northern Ireland, an assistant to a medical superintendent officer of health? Is a D.P.H. or equivalent qualification essential?

A.—No qualifications are prescribed for the post of assistant medical officer of health. The employing authority can require any qualifications which it thinks desirable. It may be assumed that an applicant must be a duly qualified medical practitioner, and if he is to be in charge of a specialized subdepartment in England and Wales he must hold the qualifications prescribed by the Local Government (Qualifications of Medical Officers and Health Visitors) Regulations, 1930, the details of which are too numerous to be dealt

with in a short answer. Such specialized appointments are unlikely to be made in an area the population of which is as low as 40,000. As already indicated, the D.P.H. is not a prescribed qualification for these posts, but if a medical officer aspires to become in time a medical officer of health he will require such a qualification, and it may be difficult for him to obtain it after he has entered the service as a whole-time officer. For this reason a very large proportion of all men or women entering the public health service in junior posts have made a practice of obtaining a public health qualification before seeking appointment as an assistant.

Inheritance of Patent Foramen Ovale

Q.—A patient aged 34 has had two infants with a patent foramen ovale and both died. What are the chances of this woman's producing another child with (a) a patent foramen ovale, and (b) any congenital defect?

A.—There is no definite evidence that patent foramen ovale is inherited, but it is almost certain that patent ductus arteriosus is inherited as a recessive, and the fact that other congenital heart lesions have occurred in more than one member of a sibship suggests that they too are inherited. It would be reasonable, therefore, to assume that the chances of another child having a patent foramen ovale are one in four, and this would be almost certain if the parents are consanguineous. It is improbable that any other congenital defect will occur.

Morphine and Adrenaline in Bronchial Asthma

Q.—In bronchial asthma 1 in 1,000 adrenaline, 0.5 c.cm., hardly ever relieves the attack. Injecting in drop doses as recommended recently is hardly practicable in private practice. Should morphine be resorted to, and, if so, is there not the danger that repeated morphine injections will lead to addiction? Apart from this, does morphine really involve the risk of suffocation by abolishing the cough reflex? How should cases that resist adrenaline be treated?

A.—The injection of 3 to 5 minims (0.18 to 0.30 c.cm.) of adrenaline usually relieves a paroxysm of asthma, particularly if given early. Bad attacks may be controlled by repeating this dose every three or four hours, or by the method of continuous injection. These methods can be taught to intelligent patients or their relations. If the attack is not controlled in this way the patient is ill enough to be in hospital or at any rate to have a nurse. Morphine is the drug of choice for cardiac asthma, but it is most dangerous in bronchial asthma, particularly in patients who are to be left. It is liable to cause death from acute respiratory failure. This is a much more real risk than addiction. The physician should ask himself why the attack is resistant to adrenaline. It may be that a bronchial infection is present, and if so one of the sulphonamides or penicillin may give relief. In other cases the reason may be an emotional upset, and solution of the mental problem will help. Failing these possibilities, the drug to use if adrenaline has not succeeded is aminophylline, gr. 7½ (0.5 g.), given very slowly intravenously, once or twice daily. Large doses of iodides or ammonium chloride may be used to loosen the tenacious sputum. Other measures include inhalations of steam, asthma powder, oxygen, oxygen and helium, etc. In very refractory cases bronchoscopy has been used to dislodge the mucus which is plugging the bronchi. If the patient cannot sleep, a barbiturate, or chloral and bromide, should be administered by mouth, or in bad cases avertin by rectum. Any of these appears safer than morphine in bronchial asthma.

INCOME TAX

Car Expenses—Assistant M.O.H.

"Phi" receives a mileage allowance of about £100 a year from his local authority, but he is considerably out of pocket as this makes no provision for depreciation. Should he take up the matter with the income-tax office?

* The fundamental point is the application of the statutory rule that to be allowable under Schedule E expenses must be "incurred wholly, exclusively, and necessarily in the performance of the duties of the office." It follows that if "Phi" uses a more expensive car than can reasonably be said to be "necessary" for his duties he cannot legally claim the full cost of running it (including depreciation, etc.) and the local authority's allowance may be enough to meet the cost of a car of the size and power which is "necessary." A claim that the allowance is insufficient is tantamount to claiming that the authority is not paying such a sum as "Phi" must necessarily incur, and we are not aware of any case in which such a contention has been successful for income-tax purposes. There may, however, be a special circumstance under present conditions—i.e., "Phi" may have had to acquire a car on the present high cost basis, though the scale allowance may be on a pre-war basis. If that is the case we consider that the allowance is demonstrably too low and "Phi" might press for a deduction from his salary on those special grounds.

LETTERS, NOTES, ETC.

Use of Liver Extracts

Dr. JOHN MILLS (Reading) writes: In "Any Questions?" (Oct. 6, p. 482; Nov. 17, p. 714; Dec. 1, p. 794) the use of liver extracts in the treatment of anaemia is discussed. Since 1930 I have had under continuous observation some 250 patients suffering from pernicious anaemia. I have tested various extracts on these patients both in relapse and under maintenance and have recorded the following observations. (1) No advantage is gained by the massive dosage in relapse advised on Oct. 6. The refined extracts I have tested have given satisfactory results on a dosage of 4 c.cm. once a fortnight, and lately I have been using a dosage of 1 c.cm. a fortnight of a certain refined extract. The crude extract used more recently has been given in an initial dose of 4 c.cm. on two successive days, and thereafter 2 c.cm. a week or 4 c.cm. a fortnight. (2) It does not follow from the observation that an extract is very active in curing a relapse that it will be satisfactory when used for maintenance treatment after the haemoglobin level has reached the normal. (3) Two crude extracts have been used over long periods for maintenance—campolon 5 c.cm. each month and plexan 2 c.cm. each month in 90% or 4 c.cm. each month in 10% of patients. Whilst on this dosage of these extracts no patient has relapsed. Several refined extracts have been used in the dosage recommended by the manufacturers and invariably several of the patients so treated have relapsed, and increasing the dose has in many cases not restored the patient to a satisfactory condition.

My conclusions are: Crude extracts are better than refined extracts, and, since massive dosage does not cure the patient more quickly, there is no justification for using it. I have suspected that unnecessarily large or frequent doses may play some part in rendering the patient sensitive to liver extracts. Testing liver extracts for maintenance value is a slow process. Certainly the answer cannot be obtained in less than two years, and I would prefer the test to run three years. Many patients must be used for each test; hence it has not been possible to test a large number of crude extracts. A greater number of refined extracts has been tested for the simple reason that the patients have relapsed and the answer been obtained usually by the end of the first year.

"He Died Peacefully . . ."

Dr. JOHN CAHILL (Middlesbrough) writes: With regard to the query under the above heading (Nov. 17, p. 712), I venture to advance the opinion that most people, at the end, die peacefully, but they hardly ever die in their sleep. At the average deathbed one witnesses a stage of agitation (accompanied, sometimes, by hallucinations, and, occasionally, by what appear to be genuine religious experience) followed by a stage of stupor deepening into coma. In deaths of catastrophic type these two stages may be of extremely brief duration and, at the other end of the scale, as in chronic uraemia, the stupor-coma stage may last for days. Thus there is no abrupt transition from consciousness to dissolution. Indeed, Disraeli showed acute perception when he wrote: "Death is most dreadful at a distance—illness weakens the mind in a wise proportion with the body."

A Missing Medical Officer

Mrs. McLELLAN (The Knowe, Mauchline, Ayrshire) would be grateful to any reader who can give information of her husband, Capt. Archibald McLellan, 159919 R.A.M.C., who has been missing in Burma since March, 1942. Capt. McLellan was wounded in that month and sent to Mandalay, but he did not arrive there and was believed to have been seen at Magwe awaiting air transport to India. The War Office state that he did not arrive in India, nor has he been found in any prison camp.

Initials

Mr. R. K. HOWAT, F.R.C.S., writes from Highgate: In your issue of Dec. 15 there is an article, "A Fatal Case of D.D.T. Poisoning in a Child," in the course of which the poisonous agent is referred to by initial letters twenty-nine times, in words not once. To one who was brought up on a technical nomenclature of words, not initial letters, this article seems an example in *excelsis* of a practice that would be welcome in *extremis*. By the way, what is D.D.T.?

* Dichloro-diphenyl-trichlorethane, for short. The full chemical name—2,2-bis (p-chlorophenyl) 1,1,1-trichlorethane—was given in the title and also in the first sentence of the preceding article on page 842 of the same issue.—ED., B.M.J.

Correction

Dr. C. HAMILTON WILKIE writes: In my letter (Dec. 22, p. 900) on the treatment of early syphilis "ten twice-weekly injections" should have read "ten double weekly injections." In other words, two injections are given at one attendance each week for ten weeks.

THE CONTRIBUTION OF ANATOMY TO THE WAR*

BY

W. E. LE GROS CLARK, F.R.S., F.R.C.S.

Department of Anatomy, University of Oxford

It is well recognized that in the war that has just ended scientists played a vastly more important part than in any previous war. In modern warfare even scientists whose subjects might seem to have only the remotest relation to military requirements are called in to give their aid. Thus the entomologist, who in peacetime studies the protective coloration of butterflies, finds his advice sought in working out the principles of camouflage. The archaeologist, who before the war excavated in remote and unfrequented parts of the world, is called upon to assist with his local knowledge of people and geography when those regions become the scene of active operations. The geologist finds himself taking part in a commando raid on the Normandy coast in order to obtain vital information about the nature of the subsoil.

In this lecture I propose to give a short survey of some of the contributions of anatomy to war problems. The survey must necessarily be brief and sketchy, since I can cover only a part of this interesting field of work. This will be apparent when I mention that in the Department of Anatomy at Oxford alone, apart from papers the publication of which was not prevented by security regulations, the number of confidential scientific reports and memoranda prepared by our staff of research workers during the war on behalf of Committees of the Medical Research Council, or of various Government Departments, etc., amounted to 104. If I here confine my attention mainly to the anatomical work done at Oxford, this is simply because I have a more intimate knowledge of it than of similar work carried out in other centres.

Anatomical Problems of Traumatic Surgery

The casualties of war necessarily focus attention on problems of traumatic surgery, not so much because these problems are essentially new, but because they may concern such large numbers of individuals in a short space of time. Thus, in every war, research workers tend to turn their attention once more to a consideration of the fundamental processes of the repair of damaged tissues and the restoration of disturbed function. No doubt each war introduces certain unusual elements into these problems, which are absent or relatively insignificant in the traumatic surgery of peacetime, such as gas gangrene, particular types of injury caused by high-velocity missiles, unusual kinds of head injury, and special features in peripheral nerve lesions; and all these continually raise new problems which require investigation. During this last war a great deal of work on fundamental processes of tissue repair has been carried out, and in many cases this has served to place clinical diagnosis and treatment on a much more sure foundation than hitherto. Since this type of work has not been governed by security considerations, most of it has been published and will be well known to the medical public. Brief reference may, however, be made to some of the results which have emerged from it.

Considering the prevalence and incapacitating effect of peripheral nerve injuries during the war, it is not surprising that this aspect of traumatic surgery has attracted a great deal of the

attention of anatomists. The comprehensive programme of experimental research into problems of nerve regeneration carried out by Prof. J. Z. Young and his collaborators at Oxford has been particularly productive. As a result we have come to learn a great deal more about the rate of growth of nerve fibres, the factors which determine or influence their maturation; the comparative values in the surgical repair of nerve injuries of autografts, homografts, predegenerated nerve grafts, frozen grafts, etc., the optimum time for surgical measures in the treatment of nerve injuries, the extent to which nerve trunks can be stretched without causing permanent damage, the factors influencing the recovery of function in the regeneration of motor nerves, and so forth.

On the sensory side the investigations of Dr. G. Weddell and his co-workers in the Department of Anatomy at Oxford have been equally illuminating. His demonstration of the complex pattern of cutaneous innervation, the multiple innervation of sensory spots, the local extension of nerve fibres into denervated areas, etc., has provided explanations of the anatomical basis of many of the sensory phenomena observed during the course of nerve regeneration. His studies of the electrical phenomena which occur in muscle at different stages of denervation and re-innervation have been of even more immediate importance, since they provide an accurate method, by means of electromyography, of assessing the extent of motor neuron damage in peripheral nerve lesions and of following the process of regeneration even before the first visible sign of returning function. The electromyograph has undoubtedly proved of great value in the diagnosis and prognosis of peripheral nerve lesions.

The problem of burns and their treatment is always a pressing one in wartime, and in the war just ended it became particularly insistent by reason of the types of weapon used. It is a remarkable fact, however, that at the beginning of the war very little information was available on the exact anatomical changes which occur in different degrees of burn, and their correlation with the toxic effects of the damage. The studies of Dr. E. H. Leach and his collaborators have served to fill up some part of this gap. They found, among other things, that the critical temperature required to produce irreversible damage to the skin is in the region of 50° C., if this is applied for three minutes. Histological evidence was also obtained that in burns of low intensity at least two visible substances are liberated from the damaged cells—a pyronine-staining substance and nucleoprotein. This liberation can occur within a few minutes of injury, and it is suggested that the pyronine-staining substance may have some relation to the H-substance of Lewis.

The demands upon the plastic surgeon in wartime are unhappily great, and the problems of skin-grafting become correspondingly more urgent. As is well known, the grafting of skin derived from another person is not successful, since the tissues do not survive transplantation between individuals of ordinary genetic diversity. It is clearly of great importance to learn what are the factors which determine this lack of survival of homografts, so that attempts may be made to neutralize them. The study of this "homograft problem" has been carried out in great detail by Dr. P. Medawar of the

* Hunterian Lecture given at the Royal College of Surgeons on Dec 13, 1945.

Department of Zoology in the University of Oxford, and the results of this work will be found in the *Journal of Anatomy*. It was demonstrated, among other things, that the mechanism by which foreign skin is eliminated belongs to the category of actively acquired immunity reactions, and the various histological processes involved in the destruction of the homografts were elucidated. These observations have led to the hypothesis that the antibody generated by skin homografts is such that it specifically prevents the completion of nuclear division in the cells of the homologous grafted skin. Now that information of this sort is becoming available, means may be devised whereby the effect of the antibody can be counteracted, thus making possible the use of homografts in the future.

As in the 1914-18 war, so in the last war, the anaerobic infections of muscles in wounds of the limbs presented a serious and difficult problem to the surgeon, and the question once more arose—How important is the factor of ischaemia in this type of infection? In spite of the fact that the direct anatomical study of injected muscles usually shows abundant anastomoses between the various vessels of supply, so that the opportunities for the rapid establishment of a collateral circulation appear good, a few clinical observers had inferred from their acquaintance with injured muscles that the several arteries supplying a muscle behave functionally as end-arteries. Experimental studies on the functional efficiency of intramuscular anastomoses in animals have now provided confirmation of this point of view, for it was found possible to produce a local and sharply circumscribed area of ischaemic necrosis in certain muscles by interrupting one of the vessels of supply or even one of its main intramuscular branches. These observations led on to a study of the intramuscular vascular pattern in human muscles, for it became clear that the surgeon should have a knowledge of such details if, when incising a muscle, he wishes to avoid unnecessary damage. But a great deal of further work must be completed on this straightforward topographical problem before all the information we require is complete.

In the course of experimental work on the vascularization of muscles the observation was made that, under certain circumstances, the regenerative capacity of striated muscle is quite remarkable. Thus, as the result of devascularization, the lower two-thirds of the tibialis anterior of a rabbit may undergo practically complete necrosis; yet in the space of three months it may be reconstituted so perfectly by the downgrowth of new fibres from the upper end of the muscle that histologically it shows little difference from the normal. This work (the results of which will also be seen in the *Journal of Anatomy*) opens up a most interesting programme of study and suggests important possibilities in the future of muscle surgery.

Some of the anatomical problems of traumatic surgery which have been dealt with during the war have been briefly outlined above. Research workers engaged in such investigations have been fortunate, since there have been no security restrictions on the publication of their results. They have thus been able to obtain full recognition for their achievements. Their anatomical colleagues who have been engaged on work of much more vital importance for the war effort have been less fortunate. Their scientific papers have been circulated within only a comparatively small circle, in the form of confidential and secret documents. Yet it is right that others should be made aware of the extent and nature of their work during the war, much of which has been extremely arduous. Indeed, this consideration provides one of the reasons for giving this lecture.

Anatomical Problems Relative to Offensive and Defensive Operations

In the earliest days of the war, before the real fighting had actually begun, little was known of the effectiveness in action of some of the modern types of weapon. Of the unknown factors which these introduced into the problem of war injuries there were two of particular importance that caused a good deal of speculation—the effect of high-velocity missiles of small size, and of blast. When casualties were first experienced in the Army, and at home in air raids, many different opinions were expressed about these effects, and it soon became a matter of some urgency that they should be carefully studied by experiment and by the statistical analysis of data

collected in the field. A programme of work directed to this end was initiated in the Department of Anatomy at Oxford and carried out under the immediate supervision of my colleague, Prof. Zuckerman, with the assistance of Dr. Delisle Burns and Dr. Krohn, and by the end of the war those engaged in it had expanded into a very busy team of research workers.

In the study of high-velocity missiles many experiments were carried out in which minute fragments of metal, weighing a small fraction of an ounce, were shot through media such as gelatin or the tissues of anaesthetized animals (the velocity being measured by the spark-photography method). These experiments demonstrated the "explosive" character of the wounds which such fragments could produce, and showed that the actual volume of damaged tissue in a wound of this kind might be many hundreds of times that of the projectile itself. The relatively large amount of tissue destruction, it appeared, is not due to the irregular shape of the missile, nor to any rotary movement which it undergoes. It is simply due to the lateral motion imparted to the particles in its track, these particles flying off radially and producing momentarily a central cavity of very low pressure. Further experiments demonstrated the vulnerability of different types of tissue to such missiles, depending on differences in their natural elasticity. Thus, comminuted fractures of the femur of a rabbit can occur even when the track of the high-velocity missile is more than 1 cm. from the bone. On the other hand, highly elastic structures, such as big arteries and to some extent nerves, are apt to escape severe damage unless they are directly hit by the missile.

These investigations were continued in order to determine the threshold incapacitating velocity for different parts of the body (protected or unprotected)—that is to say, the striking velocity of missiles necessary to produce incapacitating wounds. This required a preliminary study of the relative vulnerability of different parts of the body by reference to anatomical data and to shooting experiments with the use of such material as skulls filled with gelatin, portions of dead tissues, etc. Further, in order to get some information on the probable effectiveness of different types of weapon in the field, it became necessary to work out the mean projected area of the body which is exposed to missiles under fighting conditions. Such data were not easily come by, since, of course, in active operations in the field the body may occupy a variety of positions. However, several positions were recorded by photography and the projected areas of different parts of the body worked out. It was concluded that the mean projected area of the whole body would not exceed 4.2 sq. ft. (0.39 sq. metre) under operational conditions, that about 10 to 15% of this area represents the projection of vital organs (i.e., organs whose injury by small missiles would almost certainly cause immediate death), and that the effective vulnerable area to small fragments (that is to say, the area where immediately incapacitating wounds would be caused) amounts to about 2.8 sq. ft. (0.26 sq. metre).

It will now be apparent that by reference to (1) the relative vulnerability of different parts of the body, (2) the striking velocity of missiles necessary to produce incapacitating wounds, (3) the mean projected vulnerable area of the body, and (4) data regarding the fragmentation of explosive projectiles and the velocity of the fragments at varying distances, it is theoretically possible to estimate statistically the casualty-producing effects of the various kinds of explosive weapon. By such methods a standardized casualty rate was calculated indirectly for different types of weapon, this being defined as the average number of casualties produced where the density of the population is 1 per 1,000 sq. ft. (92.9 sq. metres). In the same way it was possible to estimate the vulnerable range of the fragments of any particular type of bomb or shell. Such estimates are not only of value in determining the tactical possibilities of weapons such as the anti-personnel bomb; they can also be applied to a calculation of the casualties likely to be experienced during air raids under different conditions. Further, they provide a basis for a computation of the probable effectiveness of body-armour and other methods of protection.

The study of the anatomical mechanisms involved in blast injuries was carried out, in the first place, on experimental animals. As a result of these observations Prof. Zuckerman,

in collaboration with other members of my department, was able to show that visceral injuries caused by blast are actually due to the direct impact of the positive-pressure wave on the body wall. The exposure of different parts of the body to the blast wave, and the protection of others by various materials such as sponge rubber, made it quite clear that, contrary to ideas which gained currency in the early part of the war, blast waves do not reach the viscera via the respiratory passages or other roundabout ways. It also became apparent that, with human beings, the threshold of lethal blast pressures was unlikely to be experienced except in the immediate vicinity of the explosion, when the danger of fatal injuries due to other causes (e.g. bomb fragments or violent displacement) would be very high indeed. These laboratory experiments were supplemented by systematic observations and the statistical analysis of the casualties caused by air raids. This aspect of the work increased as the air raids became more intensive, and by the end of the war quite an elaborate organization had been built up for collecting the necessary information. Attached to the Department of Anatomy was a team of field workers whose duty it was to go to those centres which were being exposed to bombing and to make casualty surveys on behalf of the Ministry of Home Security. Much praise is due to these young men and women for their work, which was often carried out under extreme difficulty, and, of course, was by no means without its dangers. The circumstances in which injuries were caused in air raids were subdivided into four categories: (1) primary effects due directly to the bomb itself—i.e., blast and splinters; (2) secondary effects due to displacement—i.e., being thrown violently by the force of the explosion and sustaining injuries by impact against adjacent structures; (3) tertiary effects due to secondary missiles such as flying debris or the collapse of a house; and (4) quaternary effects such as asphyxiation following burial, CO-poisoning etc. The survey showed the interesting result that most air-raid casualties were due, not to the primary effects of explosion, but to secondary and especially tertiary effects, and in spite of earlier impressions, it must have been exceedingly rare for death or serious injury to be caused by blast alone. Indeed, the conclusion was reached that human beings are much more resistant to the primary effects of the blast than are most building materials—an expression of the remarkable elasticity of the tissues of the living body.

The results of the air-raid casualty surveys, as the latter developed more and more, soon passed far beyond strictly anatomical problems. They provided data of the most valuable kind for the information of those who were busy devising protective measures. For example, a statistical analysis of the information collected by the field workers showed the sort of circumstances under which injuries were most likely to be sustained, and thus how they might best be avoided; it enabled a quantitative comparison to be made of the relative safety of different types of shelter,* or the relative risks of injury in different parts of a house (i.e., top floor, ground floor, basement, etc.); and it also provided the basis for directions to rescue squads regarding the positions at an "incident" where they would be most likely to find casualties capable of surviving if rescued quickly, and to which, therefore, they should first give their attention.

In connexion with the study of the mechanical factors concerned in producing injury to the tissues, reference may be made to certain problems which arose from time to time during the war and which made it necessary to estimate the energy required to produce fractures of different types. Thus, some casualties were caused in the field by lumps of debris thrown up by bombs which burst below the surface of the ground. The effect of such impacts was investigated, partly by experiments on animals and partly by experiments with human skulls and limb bones, and as a result it was possible to give some idea of the military effectiveness of delay-fused bombs bursting in different kinds of soil. Another problem concerned the fractures of the ankle which were said to be due to the vertical component of a ground-shock wave or the sudden upward displacement of the deck of a ship caused by

a heavy under-water explosion. In this case experiments were carried out with cadavers, with the object of assessing the value of certain protective measures which had been devised.

Fitting the Machine to the Man

The machines of modern war have become more and more complex and their mechanical efficiency and accuracy have correspondingly increased. Indeed, it is true to say that the position has now been reached where the limiting factor in the accuracy of an operation such as aiming at a moving target is not the machine but the man who operates it. If he is working at the slightest mechanical disadvantage himself he cannot make full use of the extreme degree of precision of which his machine is capable. The operator must be accurately in gear with his machine. In other words, individual machines and their operators should be integrated so as to produce a single entity working at maximum efficiency. Once this general principle is recognized it will be apparent that the anatomist is likely to be a very busy man in wartime; for each new design of gun-mounting, tank, director, etc., requires the attention of the anatomist in order to ensure that hand-controls, foot-controls, seating, and optical apparatus are accurately geared to the natural positions and movements of the human body, and that adjustments are available so that each part of the apparatus can be rapidly adapted to personnel of different body measurements. This type of research, which may be termed "fitting the machine to the man," has been carried out at several centres during the war. In the Anatomy Department at Oxford it has mainly been concerned with naval requirements, and a brief reference may be made to the sort of problem with which we were confronted.[†]

First of all it was necessary to make an extensive anthropometric survey of Service personnel in order to get adequate information on the body measurements and their range of variation which we required to know. These measurements were in many cases quite different from those which are customarily made in anthropometrical surveys; and indeed special methods, and in some cases special measuring apparatus, had to be devised. For example, we required to know the range of variation in the height of the eyes in the sitting or standing position, so that the eye-pieces of optical apparatus could be correctly positioned; the variations in different individuals of the position of the feet when the knees and hips are held at certain angles had to be studied in order to determine the optimum position of foot-controls; even such details as the width of the fist in gripping a hand-control must be known in order to determine the "knuckle-barking distance" where space is severely limited. This anthropometrical survey was carried out through the Department of Biological Research of the War Office with the collaboration of Dr. G. M. Morant.

The next problem involved the study of the amplitude of movement in those joints of the body which are specifically used in operating machines of different types, and in some cases also an assessment of the force which can be exerted by the operator at different phases of these movements. Such information is not available in textbooks, since in every case it applies to rather special circumstances. It is an interesting fact, also, that while anatomical textbooks may contain certain information regarding the movement of individual joints, they are not at all helpful in regard to the movements of joints in combination. Yet, just as it is extremely rare for a single muscle to act in isolation, so most natural movements of the human body require the co-ordinated activity of several joints together.

As an example of joint movements, we may refer here to the movements of the neck in following, say, an aeroplane through binoculars as it approaches and flies overhead. Consider the observer in the director of a battleship, whose duty it is to keep such a target fixed on the cross-wires of his sights. He sits looking through his binoculars and elevates or depresses his sight by turning a wheel. He is a most important man, since the aiming of the guns is determined by his move-

* An Anderson shelter was found in certain types of air raid to give 5 to 7 times the protection of a house, while strutted basements and trenches provided less than twice the protection of a house.

† Soon after the commencement of this work (which was carried out for the Medical Research Council, with the co-operation of gunnery officers attached to the Admiralty Gunnery Establishment and to H.M.S. *Excellent*) Dr. G. M. Weddell joined my department in order to take part in it. For the latter part of our programme he, with his assistant Dr. H. Darcus, has been mainly responsible.

ments. He should therefore be able to pin-point and follow his target with the greatest accuracy. But he cannot do this unless the pivoting of the binoculars is so adjusted that the movement of the eye-pieces in elevation and depression coincides with the natural movement of the eyes, and all straining is avoided. With the original position of the pivot we found that hardly more than 20% of personnel could elevate to 60° without strain, and that even with great straining only 75% could reach this level of elevation. It thus became necessary to analyse the neck movements afresh. This was done by cinematography. The natural track of the eye was plotted in a number of individuals of different build, and the average and the amount of variation within a 90° range of personnel determined. As might be expected, the movements of the neck in looking up and down are not simple. The centre of the movement up to about 40° elevation is in the neighbourhood of the atlanto-occipital joint, but at higher elevations it rapidly moves downwards along the spine. We found at first that by moving the pivot of the optical apparatus downwards and backwards a few inches the track of the eye-pieces corresponded much more closely to the natural track of the eyes. However, although with this new position 100% personnel could elevate to 60° without strain, not more than 60% could reach 90° even with straining, and with the development of methods of aerial attack on ships it had become an urgent requirement that operators should be able to follow their target accurately almost up to zenith. Moreover, the alteration in the position of the pivot which we suggested involved certain constructional difficulties. It was then found that the movement of the eye-pieces could be made to follow the average track of the eyes if a movable pivot was designed by fitting the sight with a cam mechanism so that above 40° elevation the binoculars would be raised with an accelerated speed. A model of this design, when tested out, proved very effective, for it enabled 90% of personnel to reach zenith, though not all could do this without a certain amount of straining.

To use a sighting apparatus efficiently, the construction of the seat in which the operator sits is a matter of extreme importance. Consider a tank-driver or a look-out on a ship, who during the course of an action may be subjected to the most violent movements and yet must somehow hold himself steady, so that he can continue to manipulate his controls and follow his target with accuracy. His ability to do so depends largely on the design of his seat. The requirements of such a seat are, briefly, as follows: (1) It must allow the operator to maintain a sitting position for periods of duty up to four hours without undue discomfort and fatigue. (2) It must permit maximum stabilization of the body while keeping the arms free to manipulate hand-controls and without restricting the mobility of the neck and upper part of the spine for sighting movements. (3) The seat level must be adjustable in relation to both the level of the binoculars and the level of the foot-rest, so as to accommodate individuals of different body dimensions. (4) It must combine lightness with mechanical strength. (5) It must stand up to very severe usage and be weatherproof.

It will thus be apparent that the problem of constructing the ideal seat is a complicated one, and we can here refer to only some of its aspects. First consider the shape of the seat. In the earlier days of the war the shaped seat, or ploughman's seat, seemed to be generally favoured for many purposes, and since its contour is meant to be adapted to the natural contour of the human bottom, it might be supposed to have the blessing of the anatomist. On the contrary, there are very serious anatomical arguments against it. In the first place, since the shape and dimensions of human bottoms vary from one individual to another, just as other parts of the body, a shaped seat can fit only one type—individuals possessing other types are bound to suffer when using the seat. Particularly is this the case with the "pommel" of the seat, which may cause serious pressure on the perineum of many individuals. Secondly, a shaped seat makes it impossible for the sitter to shift his position from time to time—a most necessary provision if fatigue and discomfort are to be minimized during long periods of duty. Thirdly, the shaped seat tends to distribute the pressure of the weight of the body over all parts of the

bottom equally, and this is anatomically quite wrong. The ischial tuberosities are designed to take the greater part of the weight in the sitting position, so as to avoid undue pressure on the soft structures, muscles, nerves, and blood vessels in the neighbourhood, and it is interesting to note that a localized area of skin over the tuberosities, like that on the soles of the feet, is particularly well supplied with arterial blood so as to minimize the risk of local ischaemia as the result of prolonged pressure.

Taking everything into consideration, there is no doubt that the ideal seat should be flat, but covered by padding which has a degree of elasticity sufficient to distribute the weight of the body over as wide an area as possible surrounding the ischial tuberosities while at the same time allowing the maximum pressure to remain concentrated over the tuberosities themselves.

Another most important element in the ideal seat is the back-rest. This must provide support for the upper part of the trunk (taking some of the weight of the body in the relaxed position), it must be accurately placed so that counter-pressure from the feet in body stabilization can be most effectively maintained, and it must allow free mobility to the thoracic and cervical spine. The optimum position and shape of the back-rest were determined by reference to anthropometric surveys, by finding out the force which can be exerted by counter-pressure from the feet in different positions, and by actual experience in the use of working models. The curve of the back-rest must not only accommodate the broadest back without cutting into the shoulder-blades, while at the same time providing adequate lateral support to the narrow back—it must also be adapted to the man encased either in heavy Arctic clothing or in the light clothing of the Tropics. The pivoting of the back-rest is not without its importance. The rest must be so pivoted that it easily follows the changing contour of the back in sighting movements, and in leaning forwards or backwards. It can be estimated, from the fact that the force exerted against the back-rest by counter-pressure from the feet is considerably greater than that derived from the weight of the upper part of the trunk, that the pivot should be a certain distance below the level of the centre of the back-rest.

In the sitting position body stabilization is an essential preliminary if the observer is to do his work accurately, and the most satisfactory method of securing it is by counter-pressure between the feet against a foot-rest and the back against a suitable back-rest. Obviously, also, the position of the legs in which the maximum counter-pressure can be developed is the ideal one for stabilization, though compromises may be necessary where adjustments have to be made for the use of optical apparatus and where space is limited. But the more the position varies from the optimum the greater the output of energy necessary to maintain equivalent pressures, since the muscles are working at a decreasing mechanical advantage. By direct experiment Dr. P. Hugh-Jones (working for the Medical Research Council at Lulworth) found that the thrust which can be exerted from the feet rises with increasing knee angles, until a quite well-defined limiting angle is reached at about 165°. Above this limit the maximum thrust falls sharply. The mean thrust possible at 165° was found to be over 500 lb. (227 kg.). Why the critical angle for counter-pressure from the feet in body stabilization should be about 165° is at first sight not clear. But it seems to be due to the fact that, with a man of average dimensions sitting in such a position, the line of the thrust passes through the pivotal axis of the back-rest when the latter is in its optimum position. If the knees are bent at a smaller angle the thrust is directed above the back-rest, so that when exerting pressure with the feet there is a tendency (which has to be restrained) for the upper part of the body to be pushed back. Conversely, if the knees are held at an angle greater than 165° the thrust tends to tilt the body forwards.

This short account of a few of the problems which are involved in the attempt to fit the machine to the man will give some indication of the not unimportant part which the anatomist plays in the design of the modern apparatus of war. Many other problems of a similar type have also been engaging attention, such as the designing and placing of different kinds

of foot- and hand-controls, methods of man-handling heavy ammunition, and the determination of the most satisfactory means whereby human energy can be utilized as a source of power in gun mountings when the main power fails. Some of these problems present no great technical difficulty, but their solution often demands much arduous work, and the results may make a very great difference to the efficiency of the men and their machines.

Application of Wartime Research Organizations to Peacetime Problems

The research organizations developed during the war for the study of anatomical and related problems have proved their worth by the fact that in a comparatively short space of time they have led to quite a number of significant advances in practical and theoretical knowledge. This being so, is it not desirable that organizations of a similar kind should be continued in times of peace? Many of the anatomical problems of war are also problems of peace, or they have their counterparts in the problems of peace. Nerve injuries, for example, are not uncommon in peacetime casualties, and even if the problems of their treatment have not the same immediate urgency for the community as in war, they certainly have the same degree of urgency for the individual. Again, the design of his seat and controls is of vital importance to the anti-aircraft gunner. But it is also of great importance to the long-distance lorry-driver in times of peace. Many other comparisons could be cited to emphasize the desirability for extending wartime organizations for research into peacetime, particularly in so far as these organizations provide for the closest possible liaison between the anatomical laboratory on the one hand, and on the other hand the clinician, the physicist, the designer of machinery, the operator of the machine, and so forth. But the continuance of research in peacetime at the rate and rhythm which it manifested in the last war depends on several factors. It depends on the availability of research personnel of high calibre, imbued with a community spirit comparable with that which characterized the research worker of the war, on financial support of the most generous kind, and on a directorate which not only ensures adequate co-ordination of workers in widely different fields of science but is also capable of supplying the inspiration necessary for successful team-work.

SYNTHETIC SUBSTITUTES FOR QUINIDINE

BY

G. S. DAWES

(From the Department of Pharmacology, Oxford)

The present shortage of quinidine has led to a search for other drugs which might be used in the treatment of auricular fibrillation. The principal obstacle to the solution of this problem has been the lack of a suitable method for testing quinidine substitutes. Various methods have been devised (for references see Wiggers and Wégria, 1940) which are laborious, require large numbers of animals, and have a rough accuracy only. A new method has been introduced in which a comparison of different substances can be made on an isolated preparation of rabbit auricles.

Method

The auricles are carefully dissected from the heart of a rabbit and suspended in a bath of oxygenated Ringer-Locke solution at 29° C.; at the upper end the auricles are fixed by an enclosed pair of platinum electrodes, just above the surface of the bath. The contraction of the muscle is recorded by means of a silk thread running round a pulley immersed in the bath, and tied to the lower end of the auricles. The auricle contracts rhythmically by itself (at a rate of 80 to 120 per minute) and can also be driven by break-shocks from an induction coil at any desired speed, using a Lewis rotary contact-breaker. As the rate of electrical stimulation is increased the auricle follows each stimulus up to a point (between 250 and 350 a minute) at which it begins to drop beats (because the interval between shocks is less than the absolute refractory period). This maximal rate at which the auricle will

follow electrical stimulation is reduced by the application, for ten minutes, of a given concentration of quinidine, and the percentage reduction of the maximal rate bears a linear relation to the logarithm of the concentration. The quinidine is only slowly eliminated from the auricle, and an interval of 45 to 60 minutes must be allowed between each observation; from 6 to 12 observations may be made on a single preparation. As the accompanying Chart shows, when the percentage reduction

Ordinates = Percentage reduction in maximal rate at which auricle responds to electrical stimuli. Abscissae = Concentration of drug on a logarithmic scale: A, Quinine; B, Quinidine; C, 2- α -naphthyl-2-hydroxyethyl piperidine hydrochloride (II); D, Butethanol.

in the maximal rate is plotted against the logarithm of the concentration the slope of the linear relation obtained for various drugs is similar enough to allow their relative activity to be expressed in a single figure. Quinidine is used as the standard for comparison on each preparation.

Results

The reduction of the maximal rate at which the auricles will follow an applied stimulus is due in the case of quinidine to a prolongation of the refractory period. The Chart illustrates the fact that quinine is only half as active as quinidine, and this is evidently the pharmacological basis for the superiority of quinidine in the treatment of auricular fibrillation.

When the question of quinidine substitutes was first considered an obvious starting-point was to take substances which had both a structural resemblance to quinidine and antimalarial activity. Dr. Harold King and Dr. T. S. Work, of the National Institute for Medical Research, Hampstead, have made a number of such substances, and have placed at my disposal specimens of 22 of these compounds. It was surprising to find that all of them possessed some degree of quinidine-like activity, whether or not they had any antimalarial action. Indeed, several were more than twice as active as quinidine. The majority of these compounds have the general formula:

where R is benzene, diphenyl, naphthalene, quinoline, or methoxyquinoline, and where N.R₁R₂ is diethylamino, dibutylamino, or piperidine, or more complex variants of the quinidine structure. There are instances in the series in which the characteristic activity is retained when the amino-group is primary or secondary, as well as tertiary. The most promising member of the series was 2- α -naphthyl-2-hydroxyethyl piperidine hydrochloride,

which had 2.8 times the activity of quinidine. Some idea of the biological variation encountered in the method may be obtained from the five individual assays on different auricles from which this mean result was calculated; these were 2.4, 2.5, 2.5, 3.1, and 3.5.

Local Anaesthetics

The observation that so many substances of Type I prolonged the refractory period of the isolated rabbit auricle gave an

entirely new outlook to the problem of finding substitutes for quinidine. MacIntosh and Work (1941) showed that many substances of Type I were powerful local anaesthetics; indeed, 2-*n*-naphthyl-2-hydroxyethyl piperidine hydrochloride (II above) was considerably more active than procaine as a local anaesthetic either on intradermal injection into the guinea-pig or on local application to the guinea-pig's cornea. Not only do compounds of Type I bear a structural resemblance to the local anaesthetics in common use, but many local anaesthetics are known to reduce the irritability of the myocardium in a manner analogous to quinidine (Kochmann and Daels, 1908; Mautz, 1936; Beck and Mautz, 1937; van Dongen, 1938; Shen and Simon, 1938; Shen, 1939; Wiggers and Wégria, 1940; Burstein and Marangoni, 1940; Hirschfelder and Tamcales, 1942).

While some of these experiments have been criticized on the grounds that relatively few animals were used, that the means of producing fibrillation were erratic, and that, as Stutzman, Allen, and Orth (1945) observed, once ventricular fibrillation had begun, injection of procaine did not necessarily stop it, yet there were ample reasons for suspecting that local anaesthetics would have an action like quinidine. So many observers, working with such different techniques, could hardly otherwise have had such uniform success with procaine.

These various considerations led to a trial of procaine on the rabbit's auricle; it was found to be only slightly less active than quinidine itself (a mean figure of 80% of the activity of quinidine on three auricles). Up to date no fewer than 19 substances which possess local anaesthetic properties have been shown to reduce the maximal rate of the rabbit's auricle, like quinidine. These include five of the compounds described by MacIntosh and Work (1941); three tertiary-amino-alkyl esters of benzoic acid made in a search for atropine substitutes (Ing, Dawes, and Wajda, 1945); cocaine (6.2); phenacaine (4.5); and butethanol (11.4), the figures in brackets indicating the mean activity assayed on five auricles each, where quinidine=1.0.

Bovet *et al.* (1939) have shown that F1262 (2-diphenyloxyethyl diethylamine hydrochloride) greatly reduces the ease with which ventricular fibrillation is induced in rabbits and dogs by electrical stimulation and that it prolongs the refractory period of the frog's heart. On the rabbit's auricle F1262 has 4.8 times the activity of quinidine (mean of five experiments); and when tested for local anaesthetic activity by intradermal injection into the guinea-pig and by the frog-plexus anaesthesia method it was found to be as active as procaine. This is not the only instance of a drug which has been tested first for quinidine-like activity on the auricle, and then, because it proved very active, been tested successfully for local anaesthetic activity.

Drugs with a Spasmolytic Action

Further consideration of the structural formulae of these compounds which had both local anaesthetic and quinidine-like activity recalled their structural similarity to trasentin and syntropan. These drugs were introduced primarily as substitutes for atropine in relieving spasm in the gastro-intestinal tract, urethra, and bladder. Trasentin is known to possess local anaesthetic activity (Gilman *et al.*, 1942), and both trasentin and syntropan were found to possess quinidine-like activity upon the auricle. Their activities relative to that of quinidine were: trasentin 60% and syntropan 130% respectively. Similarly one of the tertiary amino-alkyl esters of benzoic acid referred to above as having quinidine-like properties—benzyl oxyethyl-diethyl ammonium chloride—was found by Gilman *et al.* (1942) and Lehmann and Knoefel (1942) to be a local anaesthetic and spasmolytic. These observations suggested that other spasmolytics might act in the same way. Papaverine was found to have 50% of the activity of quinidine. Since papaverine has a benzyl-isoquinoline structure this is not quite such a profound departure as might at first appear. This observation is of all the greater interest because Wégria and Nickerson (1942) have shown that papaverine, like quinidine, increased the "fibrillation threshold" in dogs; Elek and Katz (1942) also showed that it prolonged the refractory period and decreased the irritability of the auricles and ventricles in dogs.

These findings led to a reconsideration of the action of quinidine and procaine upon the intestine. Quinidine and procaine greatly reduce the action of acetylcholine and of potassium chloride upon the isolated rabbit's intestine in a

concentration of from 1 : 100,000 to 1 : 25,000. They also cause a diminution in tone and in the pendular movements. No quantitative comparison has yet been undertaken between quinidine, procaine, trasentin, and atropine, but I think that there can be little doubt that if trasentin is to be regarded as a spasmolytic, quinidine and procaine should be classed in the same group. Similarly, Halpern (1938) and Lehmann and Knoefel (1942) have shown that many esters of amino-alcohols besides trasentin and syntropan are spasmolytics. Incidentally, Bovet *et al.* (1939) have shown that F1262 also reduces the action of acetylcholine upon the isolated intestine; this is of interest because F1262 is an example of an ether linkage between aromatic nucleus and basic group, whereas quinidine and procaine provide examples of carbinol and ester linkages.

Finally, since pethidine possesses both an aromatic nucleus and a basic group, and since it was known to have spasmolytic properties, it was tested both on the auricle and as a local anaesthetic. On the auricle it was found to have 80% of the activity of quinidine. On intradermal injection into the guinea-pig and by the frog-plexus anaesthesia method it was found to have about the same local anaesthetic activity as procaine.

Conclusion

The main purpose of this paper has been to illustrate two fundamental principles. The first is that quinidine-like activity, as measured by the rabbit-auricle method, is not a highly specific function of a particular molecular structure, but is very widely distributed among compounds possessing an aromatic (hydrophobic) group and a basic (hydrophilic) group joined by an ester, ether, or carbinol linkage, the nature of which does not seem to be of the first importance. Secondly, evidence has been brought forward to support the view that these compounds possess not only quinidine-like but also local anaesthetic and spasmolytic properties. This conclusion immediately raises the question why a good local anaesthetic (such as butethanol) should act like quinidine upon the auricle, and indeed be many times more active than quinidine. One simple explanation is that a drug which prolongs the refractory period of auricular muscle will also prolong the refractory period of nerve; if this process is continued far enough the nerve will cease to conduct, and local anaesthesia will ensue. The concentrations used support this suggestion. The concentration of procaine required to reduce the maximal rate at which the auricles will contract, without diminishing the force of contraction, is very low (1 in 100,000) compared with the concentration generally used to obtain local anaesthesia (1 in 400 to 1 in 100). A precisely similar argument might be applied to the mode of action of these drugs as spasmolytics.

This explanation of the action of, for instance, quinidine, procaine, and trasentin involves an important but not unreasonable assumption: that in living tissue, as illustrated by heart muscle, sensory nerve, and the complex arrangements of smooth muscle and nerve which make up the intestinal canal, the mode of conduction of excitation is essentially similar. Harvey (1939) has shown that quinine also prolongs the refractory period of striated muscle. By this essential similarity it is implied only that the biochemical mechanisms responsible for the conduction of excitation in these tissues are alike susceptible to reversible impairment by the action of these drugs.

One practical application of this hypothesis is of importance both clinically and in the study of new drugs of this type. If one of these compounds (structurally similar to quinidine, procaine, and trasentin) is intrinsically more active on peripheral nerves, then one would expect it to be more active on the auricle and as a spasmolytic. No doubt differences in the rate of absorption into and elimination from the various tissues cause divergencies in practice; but, broadly speaking, it is true that the more active local anaesthetics are more active on the auricle, and therefore, so far as drugs of this type are concerned, there is obviously a limit to the therapeutic index which can be reached. The better the local anaesthetic or spasmolytic, the more likely it is to have a toxic action on the heart.

Pethidine has hitherto been regarded essentially as a morphine substitute, with the very useful property of relaxing smooth muscle. The observation that pethidine possesses local anaesthetic and quinidine-like properties as well alters the position radically. Many of the local anaesthetics have a depressant

action upon the central nervous system: is pethidine a particularly favourable instance? Are its anaesthetic properties due to a prolongation of the refractory period in the central nervous system?

[A fuller account of this work, with details of relative activities and toxicities, from the point of view of choosing a quinidine substitute for clinical trial, will be published shortly.]

Summary

A method is described for measuring the potency of drugs as substitutes for quinidine, using the isolated auricles of the rabbit.

A large number of quinidine substitutes have been studied. These comprise many of the local anaesthetics and spasmolytics in common use. Some of these are very much more active than quinidine on the auricle—e.g., butethanol is more than ten times as active.

Pethidine possesses both local anaesthetic properties and a quinidine-like action on the auricle.

These findings suggest that the transmission of excitation is essentially similar in auricle and sensory nerve (and perhaps in the wall of the intestinal tract), in that it is susceptible to a reversible depression by the same drugs.

This work was carried out during the tenure of a grant from the Medical Research Council.

I am much indebted to Dr. H. King, F.R.S., and Dr. T. S. Work for the 22 quinidine analogues with which the investigation was begun; to Dr. Daniel Bovet for the F1262; and to Dr. H. R. Ing for three tertiary-amino esters of benzoic acid. I am also most grateful to Prof. J. H. Burn for the advice and encouragement which he has given throughout.

POISONING BY AMANITA PHALLOIDES

BY

JAL DUBASH, M.D., D.C.P., D.T.M.&H.

Pathologist, Borough General Hospital, Ipswich

AND

DONALD TEARE, M.B., M.R.C.P.

Assistant Pathologist, St. George's Hospital

Poisoning by fungi mistaken for edible mushrooms is comparatively rare in Great Britain. Reviewing the French literature, however, Ford (1923) collected 990 cases, 381 of which were fatal. The position was so serious in France that in 1925 a law was enacted providing that there should be inspectors at all market towns, to pass mushrooms as fit for human consumption. The efficacy of this law can be judged by the fact that in 1930 the mushroom inspector at Fougères died of fungus-poisoning.

Few cases have been reported in the medical press in this country, but in the London daily press the following cases have appeared in the past 15 years:

Date	Place	Fatal Cases	Associated Non-fatal Cases
Aug., 1930	Mildenhall	Boy of 6	One
" "	Cambridge	Man of 38	
" "	Methwold	3 girl guides	
July, 1933	Warrington	Girl of 7	Three
Aug., 1934	Monmouth	Woman of 45	
July, 1937	Leatherhead	Man of 36	
Aug., 1939	Stow Bedon	Father, son, and housekeeper	Three
Aug., 1941	Potton	Girl of 9	
Aug., 1942	Ponders End	Child of 5	
Oct., 1942	Chorley Wood	Man of 56	

A total of 21 cases, with 14 deaths

Mycology

There are three species included in the genus *Amanita*—*Amanita phalloides*, *Amanita verna*, and *Amanita virosa*. *Amanita phalloides* (Fig. 1) is more commonly known as the

FIG. 1—Death-cap (*Amanita phalloides*).

FIG. 2—Mushroom (*Psalliota campestris*).

"death-cap." It can be found in any soil, but prefers chalk. It is often seen in association with oak trees. Typically, it is a large fungus with a smooth greeny-orange-coloured cap, and fine brown or black markings radiating from the centre. The gills on the under surface are white with a slight greenish or

yellowish sheen. The stalk is smooth, with a bulblike expansion at the base. In its upper part is a large thin white frill at the ring. The base is surrounded by the volva. When fresh this fungus is odourless and tasteless. It must be remembered that there are aberrant forms of the fungus; the colour may range from pure white to yellow.

The commonest edible fungus to be confused with *Amanita phalloides* is the field mushroom (*Psalliota campestris*) (Fig. 2). The chief characteristics of *Psalliota* are as follows: The cap is convex at first, and as it matures becomes flattened. It is white or brownish in colour, and is covered with silky fibrils. Later the surface of the cap becomes scaly. The stem is white, with a membranous ring. In the early stages the gills are white, becoming pink or purplish and finally almost black. The *Psalliota campestris* usually grows in meadows.

According to Hoechstetter (1943) and Nobécourt and Martin-Lipmann (1940) *Amanita phalloides* contains two toxins—one which is thermostable and resembles the action of phosphorus, and the other a haemolysin which is thermolabile. According to Ford, the haemolysin is rapidly destroyed by the action of heat, weak acids and alkalis, and digestive juices. He concluded that the haemolysin plays only a subsidiary part in the poisoning by *Amanita phalloides*, the main factor being the heat-resistant toxin. The injection of this toxin in an animal reproduces the signs and histological lesions of *Amanita phalloides* poisoning. Lynen and Wieland (1937) describe two other poisonous derivatives of *Amanita phalloides*, whose action does not appear to have played any part in the cases under review.

The four patients whose cases are here reported all died from liver damage, similar to that described by Vander Veer and Farley (1935) and Ahronheim (1938), and indistinguishable from acute yellow atrophy. In these cases the fungi had been cooked and the changes found at necropsy were undoubtedly due to the heat-resistant *Amanita* toxin.

Case I

Miss A., aged 26, a lorry-driver, was admitted to the Borough General Hospital, Ipswich, on Oct. 10, 1944, at 11.45 a.m. The evening before admission she had picked about 35 "mushrooms" in a wood near Ipswich; some of these were examined later and were found to be *Amanita phalloides*. The fungi were eaten for tea at 6 p.m. on Oct. 9. At about midnight she was taken ill with vomiting; diarrhoea started two hours later. The stools were frequent—at first formed, but later containing mucus only.

On examination she was peculiarly grey and cyanosed. Vomiting had stopped. The pulse was 72, the temperature 97°, respirations 20, and blood pressure 90/70. The tongue was thickly furred and the abdomen slightly distended; there was no tenderness. Nothing abnormal was detected in the chest. The patient was in fairly good condition, sensible, and not distressed. Gastric lavage was performed and 50 c.cm. of 50% glucose was given intravenously. Atropine 1/50 gr. (1.3 mg.) was given four-hourly. Ten units of insulin covered by 40 g. of glucose was administered thrice daily.

Next morning the patient started vomiting. She vomited 130 fl. oz. (3.6 litres) in 24 hours, and the pulse rose from 80 to 104. She was put on a glucose-saline drip. The urine was found to contain albumin and acetone. The dose of atropine was now reduced to 1/100 gr. (0.65 mg.) four-hourly. On Oct. 12 the signs of peripheral circulatory failure were more pronounced. The blood urea was 150 mg. per 100 c.cm. and the blood sodium 276 mg. The urine contained 20 mg. of albumin per 100 c.cm. and a fair number of hyaline and granular casts, with epithelial debris. No blood cells were seen. The glucose-saline drip was continued and nikethamide and percutone were given. An electrocardiogram showed no gross myocardial disturbance. The pulse rate was 80, the rhythm regular, and the tracings of low voltage. This investigation was carried out in view of Hyman's (1928) report of temporary right-sided bundle-branch block in *Amanita*-poisoning.

On Oct. 13 the patient appeared to be drowsy. Blood pressure, 100/60. Blood urea, 160 mg. per 100 c.cm. Blood count: R.B.C., 6,400,000/c.mm.; W.B.C., 6,000/c.mm.; haemoglobin, 120% (17.4 g. %); colour index, 0.9. In the afternoon her condition suddenly deteriorated; she became irrational and was difficult to keep in bed. The pulse was not perceptible. The blood pressure was 70/?, and during the night the patient was in coma. She died at 9.30 a.m. on Oct. 14—111 hours after eating the fungus.

Post-mortem Examination.—This was performed three hours after death. There was a peculiar cyanotic change in the face. On opening the body a very marked red staining was found—possible laking of the blood by *Amanita phalloides* toxin. Spectroscopic examination of the blood showed no abnormal bands. The pericardium

showed large petechial haemorrhages. The right side of the heart was slightly dilated. The heart muscles appeared paler than normal, but were not friable. No valvular disease was found. The lungs were extremely congested and oedematous. Both apices showed consolidation and marked petechial haemorrhages. In the stomach was a very severe degree of haemorrhagic gastritis. The ileum and colon had undergone inflammatory changes, with petechial haemorrhages and some free blood. The liver was much reduced in size (weight 1,000 g.); it was pale yellow and very friable, showing obvious acute yellow atrophy. The kidneys were enlarged and whitish in colour, with petechial haemorrhages on the surface. The spleen appeared normal.

Histological Findings.—Major histological changes were found in the liver and kidney. In the former, except for occasional small sharply defined islands around some portal systems, the whole of the tissue was abnormal. The liver cells were pale and empty-looking, suggesting fatty changes. Their nuclei were hydropic and often distorted in shape. All degrees of karyolysis were seen. Many scattered liver cells had undergone necrosis, and dead cells containing yellow pigment were seen. Throughout the section there was a slight excess of polymorphonuclear leucocytes. The bile ducts and blood vessels appeared normal. Section of the kidney showed much parenchymatous degeneration and congestion, especially in the medulla. Yellow pigment was abundant, particularly at the base of the cells of the tubular epithelium. In the cortex the tubules were more widely separated than usual, probably by oedema of the interstitial tissue, and there were many dilated vessels and lymphatics.

Case II

Mrs. B., aged 38, was admitted to the Borough General Hospital, Ipswich, on Oct. 10, 1944, at 11.45 a.m., with exactly the same history as Case I. On examination she was rather cyanosed and had continuous diarrhoea and vomiting. She was treated with atropine 1/50 gr. (1.3 mg.) and atropine 1/100 gr. (0.65 mg.) four-hourly. The stomach was washed out and magnesium sulphate given. Ten units of insulin covered with 40 g. of glucose was administered thrice daily, also 300 g. of glucose by mouth. On Oct. 11 the vomiting appeared to be controlled by atropine. There were frequent offensive mucoid stools and the patient was still very cyanosed.

On Oct. 12 the blood urea was 140 mg. per 100 c.cm. and the blood sodium 260 mg. Urine: No red or white cells; a large number of hyaline casts were present; albumin, 20 mg. per 100 c.cm.; culture remained sterile. Vomiting did not recur, but the patient was very weak and complained of pain in the back of the chest. During the day peripheral circulatory failure set in, the pulse became imperceptible, and the blood pressure could not be recorded. The patient was orthopnoeic and shocked, and coarse crepitations could be heard at both bases. Nikethamide and percutone were given, but the patient's condition continued to deteriorate, and she died at 10 p.m.—76 hours after eating the fungus.

The necropsy findings were exactly the same as in Case I. Here again the peculiar red laking effect of the blood was seen. There was no blood-clotting. Spectroscopic examination of the blood before and after death showed no evidence of any abnormal pigment. The histological findings of the liver and kidney were the same as in Case I.

Case III

A Polish Jewess aged 57 was admitted to St. Charles's Hospital at 10 a.m. on Sept. 26, 1944, with a history of having eaten "mushrooms" collected at Henley-on-Thames. The day before admission the daughter of the house cooked some of these "mushrooms," but put away four or five, which she distrusted. The family partook of a meal of the "mushrooms" with no ill effects. The same evening the deceased prepared the doubtful "mushrooms" by frying them in butter, and ate the lot herself. About eight hours after the meal she was taken ill with severe abdominal pains, diarrhoea, and vomiting. She was admitted to the hospital at 10 a.m. the next morning and was given a dose of castor oil.

About 1½ hours after admission her condition rapidly deteriorated, with exacerbation of diarrhoea and vomiting and pain in the epigastrium and the right iliac fossa. The pulse was rapid and feeble, and the systolic blood pressure was 70 mm. Hg. The diastolic pressure did not register. The patient was almost pulseless. Throughout Sept. 27 she was still almost pulseless, vomiting mucus, and had frequent diarrhoea. Intravenous plasma was given. On Sept. 28 diarrhoea ceased and some fluid was retained by mouth; the pulse continued to be feeble. On Sept. 29 her condition was much the same, but she became restless during the night. On Sept. 30 the patient was alternately restless and drowsy until she lapsed into coma and died at 11.35 p.m.—126 hours after the fatal meal.

Necropsy was performed two days later. The body was that of an adequately nourished adult woman. She was cyanosed and of ashen-grey complexion. The meninges were very congested. Several

small petechial haemorrhages were seen on the posterior surface of the heart, which was slightly dilated in all its chambers, the muscle was somewhat friable. The valves and vessels were normal. The stomach contained some grey mucous material. A few small petechial haemorrhages were seen in the gastric mucosa. The terminal ileum and colon showed no inflammation with numerous small haemorrhages in the mucosa. The liver was much reduced in size, weighing only 840 g. It was brown in colour, with a slightly nodular surface, and had a few small areas of haemorrhage. The kidneys were mottled and hyperemic, the spleen and suprarenals were normal. Microscopically there was gross destruction of liver parenchyma. Indeed, it was difficult to identify a healthy liver cell. Fatty degeneration was very marked, and small haemorrhages were collected round the portal vein. The kidneys showed vast cloudy swelling of the tubules, with encroachment of glomeruli and some escape of red cells into the tubules. The contents of the colon revealed large numbers of spores which were morphologically indistinguishable from those of *Amanita phalloides*.

Case IV

On Aug. 18, 1945, a girl aged 6 had tea with an uncle and aunt at Walling Cross. Her uncle had brought home some mushrooms (about 1/2 lb (225 g)) which he had picked at Arborfield, near Reading. The aunt cooked the 'mushrooms' in a little fat and water for tea which was eaten by all three. At about 9.30 o'clock the same evening the girl was taken ill with diarrhoea and vomiting, and shortly afterwards the two adults developed the same symptoms. The child and one adult remained very ill throughout the 19th and on the 20th the child's mother was sent for and took her home. A doctor was called and he prescribed some medicine. The child's condition was so bad at four o'clock on the morning of the 21st that the doctor was again called, and he arranged for her admission to hospital. She reached hospital at 6.30 a.m. in a collapsed and cyanotic condition, and was given 1/100 gr (0.65 mg) of atropine and gastric lavage was performed, but she died half an hour later—rather more than 60 hours after taking the alleged mushrooms.

Necropsy showed the girl to have been icteric and nystreous. There was a very marked dusky cyanosis in the hypostatic parts of the body and also in the face and front of the arms. The meninges and brain were intensely congested and purple in colour. There were several small petechial haemorrhages on the back of the heart, the right side of which was acutely dilated and contained a large quantity of extremely dark blood clot. Scattered petechial haemorrhages were found over the surface of the lungs, and also numerous large areas of collapse, which were particularly marked over the back of the right lung and the lower lobe of the left. The lungs throughout were intensely congested. Several small haemorrhages were present in the anterior mediastinum. Numerous petechial haemorrhages were seen throughout the mesentery and omentum, they were mainly concentrated at the junction of the small intestine with the mesenter. The liver weighed 656 g and showed very advanced fatty change in which numerous small haemorrhages could be seen, it was in fact, a typical picture of really acute liver destruction. There was a mild degree of inflammation throughout the intestinal tract—most severe in the transverse colon. The kidneys were intensely congested otherwise normal macroscopically. Sections of the liver showed an extraordinary degree of fatty degeneration with numerous small haemorrhages throughout the liver tissue. There was marked cloudy swelling of the renal tubules. Spores morphologically identical with those of *Amanita phalloides* were seen in the intestinal contents.

Discussion

In all four cases the main lesion appeared to be a severe toxic action on the liver and kidneys, leading to the rapid appearance of renal and hepatic failure. One striking feature was the constancy of the time factor between the ingestion of the poison the onset of symptoms, and death. The latent period before the appearance of symptoms of phallin poisoning was characteristically of 6 to 12 hours' duration. The initial symptom complex of vomiting, diarrhoea, and collapse was very constant. Gradually the clinical picture became dominated by signs and symptoms of liver and kidney damage. Other authors have described cases with marked jaundice and diarrhoea. Again, cases in which the picture was one of damage to the central nervous system with convulsions and generalized clonic spasms have been described—'forme pseudo-tétanique'.

Symptomatic Treatment.—Symptomatic treatment plays a very great part. It is directed towards removing as much of the toxin as possible by stomach washouts in the early stages. Only purgation, which is said to hinder absorption of the toxin, seems to be a rational measure. Intravenous therapy is necessary to combat the circulatory failure, prevent dehydration and induce diuresis. No effort should be spared to promote excretion by

the kidneys. Alcohol is contraindicated, as it favours the absorption of toxins.

Organic Therapy.—The use of a mixture of fresh mixed stomach and brain of rabbit in the treatment of phallin poisoning would seem to approach witch-doctoring, but this mixture is still popular in parts of France. The apparent immunity of rabbits to the ingestion of *Amanita phalloides* in the field appears to be the basis of this treatment, yet it seems rather anomalous that the rabbit has been used more than any other animal in experimental work on phallin poisoning. A mixture of three stomachs and seven brains appears to be the most popular combination. Brain alone does not seem to have the desired effect, or the power of lipid to absorb the poison might be the explanation.

Serotherapy.—The chief difficulty associated with serotherapy, in the treatment of phallin poisoning lies in the fact that supplies of serum cannot be continually available in the remote districts where cases are liable to occur, in common with most other diseases, the interval between onset and injection is very significant. However, numerous attempts have been made to produce an antiserum, and as long ago as 1897 Calmette increased the resistance of rabbits to the ingestion of *Amanita phalloides* by previously injecting them with an extract of macerated fungus. Dujaime de la Riviere (1933) produced his antiphallidien serum by inoculating a horse. This serum appears to have had excellent results when given within a reasonable time of onset of symptoms.

Summary

Four cases of *Amanita phalloides* poisoning are reported, with pathological findings.

Amanita phalloides is contrasted with the field mushroom, and its poisons are described.

The main methods of treatment are reviewed.

We wish to thank Mr. Cunard T. Dawson, coroner for the Borough of Ipswich, Mr. H. G. Broadbridge, coroner for the West of Dorset, Mr. J. P. Hulme, deputy coroner for the West of Division of London, for permission to publish the cases.

THE SOLUBILITY OF SULPHONAMIDES IN RELATION TO HYDROGEN-ION CONCENTRATION

BY

H. A. KREBS, M.A., M.D.
 Professor of Biochemistry

AND

J. C. SPEAKMAN, M.Sc., Ph.D.
 Lecturer in Chemistry
 University of Sheffield

Recent publications on the solubility of sulphonamides in urine (Gillman and Plummer, 1943; Jensen and Fox, 1943; Medical Research Council War Memorandum No. 10, 1945; Schmidt *et al.* 1944; Burn, 1945) show that the problem of the effect of pH on solubility has not yet been tackled from a general theoretical point of view. It has been empirically found that the solubility of sulphonamides rises as a rule, with increasing alkalinity. Fox and Rose (1942) and Jensen and Fox (1943) point out that this effect can be explained by the fact that most sulphonamides are weak acids which form readily soluble salts within the physiological pH range of urine. As the salt formation usually increases within the physiological limits of pH, the solubility also increases with pH. Previous authors, however, offer no quantitative theory for the effect of pH on solubility.

It is the object of this paper to show that the problem of the relation between pH and the solubility of sulphonamides lends itself to a general treatment in accordance with simple physico-chemical principles. The solubility at a given pH can be predicted from two constants: (1) the solubility of the undissociated sulphonamide; (2) the (classical) acid dissociation constant of the sulphonamide. These two constants can be obtained from two (or more) solubility measurements at different H-ion concentrations.

Sulphonamides as Electrolytes

The majority of the sulphonamide drugs are ampholytes (i.e., both acids and bases), though some are bases only—e.g., sulphaguanidine—and other acids only—e.g., sulphasuxidine. The basic properties of simple sulphonamides are associated with the *p*-amino group, the acidic properties with an H atom in the sulphonamide group. Substituents may abolish these functions and add further basic or acidic groups. For physiological considerations most sulphonamides can be treated as monobasic acids dissociating according to

The basic functions of the molecule, or such second acidic functions as may be present, are as a rule not operative within the physiological range of pH.

While the un-ionized forms of sulphonamides are usually sparingly soluble, the ionized sulphonamide salts, formed on addition of alkali, are usually readily soluble. A few examples are given in Table I.

TABLE I.—Solubility of the Undissociated and Ionized Forms of Sulphonamides

Sulphonamide	Solubility (37° C.) (mg. in 100 ml.)	
	Acid	Salt
Sulphapyridine	52	About 25,000
Sulphathiazole	96	" 25,000
Sulphadiazine	15	" 30,000
Sulphamezathine	190	" 20,000

The data are taken from the Medical Research Council War Memorandum, "The Medical Use of Sulphonamides"; they are approximate values.

Quantitative Theory of Solubility

We assume that sulphonamides are monobasic acids, and we let HA represent the un-ionized and A⁻ the ionized form. The relationship between the concentrations of HA and A⁻ in any solution is governed by the equilibrium

Applying the law of mass action we obtain

$$K_A = \frac{[\text{H}^+][\text{A}^-]}{[\text{HA}]}, \quad (2)$$

where [] represent concentrations and K_A is the (classical) acid dissociation constant. In a saturated solution the dissolved substance is, in principle, in equilibrium with the solid:

Therefore the total solubility (S) is given by

$$S = [\text{HA}] + [\text{A}^-], \quad (3)$$

where [HA] is a constant for a given solvent and a given temperature, and may be represented by

$$S^0 = [\text{HA}]. \quad (4)$$

Combining (2), (3), and (4),

$$S = S^0 + \frac{K_A S^0}{[\text{H}^+]}. \quad (5)$$

As it is customary to use, instead of K_A and [H⁺], the corresponding negative logarithm, pK and pH, it is convenient to replace [H⁺] by 10^{-pH} and K_A by 10^{-pK_A}, where

$$S = S^0 (1 + 10^{pH-pK_A}). \quad (6)$$

With the help of (5) or (6) the total solubility of a sulphonamide at different H-ion concentrations can be calculated if S⁰ the solubility of the un-ionized form and K_A are known.

Determination of S⁰ and K_A

When the compound shows only acidic properties S⁰ can be determined by measuring the solubility at a pH at least 3 units below pK_A. When the compound is an ampholyte this may not be possible because the solubility rises again below the iso-electric point. The solubility should then be measured at a pH near the iso-electric point on the alkaline side, and a correction should be applied in accordance with (8). As a rule S⁰ is not very different from S in water, since in the absence of other buffers the sulphonamide itself causes the water to assume a pH near the iso-electric point.

In theory K_A can be determined by the usual methods for the measurement of dissociation constants (Bell and Roblin, 1942). In practice the application of these methods to sulphonamides is somewhat inconvenient because of the low solubility of these compounds. A more convenient method giving both K_A and S⁰ consists, in principle, of making two measurements of the total solubility, S' and S'' at [H⁺]' and [H⁺]''. Using a rearranged version of (5), we may write

$$S^0 = \frac{S'}{1 + \frac{K_A}{[\text{H}^+]'}} = \frac{S''}{1 + \frac{K_A}{[\text{H}^+]''}}.$$

Therefore

$$K_A = \frac{S'' - S'}{\frac{S'}{[\text{H}^+]''} - \frac{S'}{[\text{H}^+]'}}. \quad (7)$$

When K_A has been calculated, S⁰ can be obtained with the help of the following version of (6):

$$S^0 = \frac{S}{1 + 10^{pH-pK_A}}. \quad (8)$$

Equations (7) and (8) enable us to calculate S⁰ and K_A from two solubility measurements at two different H-ion concentrations. For the sake of accuracy more than two sets of data are desirable, and with a series of data it is more convenient to find S⁰ and K_A graphically instead of using (7) and (8).

According to (5), a plot of S against $\frac{1}{[\text{H}^+]}$ gives a straight line intersecting the S axis at S⁰ with a slope a (S⁰K_A), whence K_A can also be found. Alternatively, rearranging (5), we obtain

$$\log \left(\frac{S}{S^0} - 1 \right) = pH - pK_A$$

so that a plot of $\log \left(\frac{S}{S^0} - 1 \right)$ against pH gives a straight line of unit slope intersecting the pH axis at pK_A.

Test of the Theory

Data published by Gilligan and Plummer (1943) for the solubility of sulphadiazine in buffer solutions of different pH can be used to test the theory. In accordance with the theory straight lines were obtained when the graphical methods were applied. S⁰ was found to be 12 mg. per 100 ml. and pK_A to be 6.33. Table II shows that the observed and calculated solubilities are in satisfactory agreement. The theory is also confirmed by our own series of measurements, which have been published elsewhere, together with a more rigorous treatment of the theory (Krebs and Speakman, 1945).

TABLE II.—Solubility of Sulphadiazine in Buffer Solutions at 37° C.*

pH	S Observed	S ⁰ Calculated
5.25	13	13
5.50	14	14
5.70	15	15
6.12	19	19
6.38	26	26
6.90	53	57
7.20	102	101
7.30	136	124
7.85	383	393

* Measurements of solubility taken from a graph in the paper of Gilligan and Plummer (1943). Calculations based on assumption that S⁰ = 12 mg/100 ml; pK_A 37° = 6.33. S is expressed in mg. sulphadiazine in 100 ml.

K_A and S⁰ of Sulphonamides and their N⁴-acetyl Derivatives. Knowledge of K_A and S⁰ of the sulphonamides and their acetyl derivatives will thus enable us to predict approximately

the solubility of the drugs in body fluids whose pH is known. We have therefore measured the necessary constants for the more common sulphonamides and their N'-acetyl derivatives. The measurements were made in buffer solutions of a total ionic strength of 0.1 M. When the theory is applied to urine it has to be borne in mind that pK_a will be slightly affected by other solutes which contribute to the ionic strength, pK_a will therefore show slight variations from urine to urine, which may, however, be neglected for practical purposes. The solubility will also be affected by substances in the urine which combine with sulphonamides. Among these urea is probably the most important one. The solubility of sulphamerazine in serum was found to be almost the same as in buffer solutions, which indicates that serum proteins have no appreciable effect on the solubility. This is somewhat unexpected in view of the alleged "binding" of sulphamerazine by serum protein.

The results of the measurements of K_a and S° are shown in Table III. The data for pK_a are not very different from those reported by Bell and Roblin (1942) for 25°, while the data for S° roughly agree with the solubilities in water reported in the literature. It will be noted that the pK_a of the N'-acetyl compounds is in every case smaller than the pK_a of the "free" sulphonamides; in other words, the acetyl derivatives are stronger acids than the parent substances.

TABLE III—Acid Dissociation Constants (pK_a) of Sulphonamides, and their N'-acetyl Derivatives and Solubilities of Undissociated Compounds (S° at 38°) (pK_a refers to the Carboxyl Dissociation Constant, Ionic Strength=0.1 M)

Drug	pK_a	S° (mg. in 100 ml.)
Sulphadiazine	6.28	9.9
N'-acetyl sulphadiazine	5.16	15.6
Sulphathiazole	7.10	92
N'-acetyl sulphathiazole	6.81	71
Sulphamerazine	7.38	64
N'-acetyl sulphamerazine	7.14	84
Sulphamerazine	6.95	41
N'-acetyl sulphamerazine	6.55	80
Sulphapyridine	8.32	30
N'-acetyl sulphapyridine	8.02	31
Sulphasuxidine	4.48*	49

* Refers to the dissociation of the carboxyl group of the succinyl radical.

From the data given in Table III it is possible, with the help of (5) and (6), to calculate the solubilities within the physiologically relevant range of pH. Table IV gives the calculated solubilities at pH 7.4—the approximate pH of blood plasma—and of the contents of the small intestine—and at pH 6.4—a degree of acidity often found in urine.

TABLE IV—Solubilities of Sulphonamides (calculated)

Drug	pH 7.4	pH 6.4
Sulphadiazine	140	23
N'-acetyl sulphadiazine	664	83
Sulphathiazole	276	1.88
N'-acetyl sulphathiazole	35	9.9
Sulphamerazine	131	74
N'-acetyl sulphamerazine	237	99
Sulphamerazine	157	53
N'-acetyl sulphamerazine	646	137
Sulphapyridine	56	51
N'-acetyl sulphapyridine	39	22

Nomogram

In order to facilitate the calculation of S (though with some loss of accuracy), a universal chart has been constructed covering the more important range of the common sulphonamides. Any straight line drawn across the diagram intersects the three scales at values of ($pH - pK_a$), S° , and S which satisfy equation (6). Hence when ($pH - pK_a$) and S° are known the nomogram here reproduced may be used for calculating S with an accuracy sufficient for most purposes. For example, find the solubility of sulphadiazine at pH 7.0 (38°). In this case $pH - pK_a = 7.00$

$-6.28 = -0.72$, and $S^\circ = 9.9$. A straight line from the point -0.72 on the $pH - pK_a$ scale to the point 9.9 on the S° scale, when produced, intersects the S scale at 62. This is the solubility at pH 7.0. It is convenient to use a stretched thread for the geometrical operation.

General Validity of the Theory

The theory of solubility of sulphonamides proposed in this paper is applicable to other substances. Of pharmacological interest is the application to drugs which (1) are weak acids or bases with a pK_a or pK_b between 6 and 8, (2) are sparingly soluble in their undissociated form but readily soluble in the dissociated form. Among the acids a number of narcotics—among the bases quinine and other alkaloids—belong to this category.

Dissociation Constant and Physiological Properties

Bell and Roblin (1942) and Schmelkes *et al.* (1942) have pointed out that the dissociation constant of N'-substituted sulphonamides is one of the factors controlling the bacteriostatic properties. Bell and Roblin produce evidence in support

Nomogram for the rapid evaluation of the solubilities of sulphonamides

of the hypothesis that the more negative the SO_2 group of a sulphonamide, the greater the bacteriostatic activity. As the SO_2 group of a given sulphonamide is more negative in the ionized form than in the un-ionized form, the dissociation constant must influence the bacteriostatic activity.

The dissociation constants are liable to affect a variety of other pharmacological properties of the drugs, especially their distribution in the body (Shannon, 1943). Some observations on the absorption from the intestine can be explained if it is assumed that absorption is facilitated by the ionization of the sulphonamide group. Sulphapyridine has been reported to be absorbed more slowly, less regularly, and less completely than sulphathiazole and sulphadiazine (see Hawking, 1945). At the pH prevailing in the small intestine sulphapyridine is largely un-ionized, while sulphathiazole and sulphadiazine are mainly present as anions. Particularly striking is the non-absorption of the drugs of the sulphaguanidine and sulphasuxidine groups. Marshall *et al.* (1940) found empirically that sulphaguanidine (as well as N^1 -(2-hydroxyethyl)-sulphapyridine and N^1 -diglycol-sulphapyridine) are poorly absorbed. In these compounds both H atoms of the $-\text{SO}_2\text{NH}_2$ group are substituted and the acidic properties of this group are therefore abolished. In sulphasuxidine, sulphathalidine, and sulphanilyl sulphanilate the acid properties of the SO_2 group are so weakened by the introduction of another acidic radical into the molecule that they do not come into play under physiological conditions. It is thus very suggestive to think that the non-absorption of sulphaguanidine, sulphasuxidine, and allied compounds is related to the non-ionization of the $-\text{SO}_2\text{N}<$ group.

The penetration of sulphonamides into the cerebrospinal fluid and their distribution between blood plasma and blood cells are further aspects deserving of examination from the same point of view. More experimental data are required, however, before the problem can be usefully discussed.

Summary

It is shown that the approximate solubility of sulphonamides in aqueous solutions of different pH can be predicted from two constants—the solubility of the undissociated sulphonamide and the acid dissociation constant. Agreement between observed and predicted values is satisfactory.

A method for the determination of the two constants is described and the values of the constants are given for the more commonly used sulphonamides and their N^1 -acetyl derivatives.

It is pointed out that the acid dissociation constants of sulphonamides affect certain pharmacological properties. The non-absorption of the drugs of the sulphaguanidine and sulphasuxidine groups appears to be related to the non-ionization of the $-\text{SO}_2\text{N}<$ group.

The Public Health Committee of the Edinburgh Town Council, as reported in the *Scotsman*, has had before it details of two new medical schemes. One is for the provision of orthopaedic services. A joint committee of local authorities and voluntary organizations recommended the appointment of a director of orthopaedics for the area who shall also be a reader in orthopaedics in the University of Edinburgh. The Public Health Committee approved the proposals and empowered the joint committee to appoint a suitable applicant in collaboration with the University Court. The other scheme, proposed by the University in conjunction with Edinburgh Corporation, is that one of the chairs of medicine in the University should be devoted to teaching, care of patients, and clinical research solely in connexion with the municipal general hospitals. To put this proposal into effect building developments would be essential at the Western General Hospital. The Public Health Committee, agreeing in principle to the proposals outlined, resolved that the arrangements should be examined in greater detail with a view to making the necessary adjustments between the Corporation and the University.

PENICILLIN CREAM OF LOW CONCENTRATION

BY

G. H. du BOULAY, M.B.

This analysis of 39 cases of staphylococcal and streptococcal infection of the skin, treated with a penicillin cream containing 200 units of penicillin per ml., was carried out at Charing Cross Hospital. The application used was made up as follows:

Lanette wax	3.5 g.
Liquid paraffin	15 ml.
Penicillin solution	5 ml.
Phenoxetol	2 ml.
Aqua redest.	ad 100 ml.

and was spread over the infected skin twice a day after the area had been thoroughly washed with warm water and soap.

In order that the clinical observations should not be influenced by the bacteriological findings, the diagnosis was made and the treatment prescribed on clinical grounds alone; and although the culture was taken at the time of the patient's first visit, the report was not seen until he had been under treatment for a fortnight. Later it was discovered that this routine was no disadvantage to the occasional patient harbouring penicillin-resistant organisms, but the reverse, because some improvement was gained in every case during the first week.

The cases recorded are: impetigo, 20; sycosis barbae, 5; infection superimposed on previous disease or trauma, 10; otitis externa, 2; retro-aural intertrigo, 2.

Impetigo

1. *Penicillin-resistant Strains of Staph. aureus*.—Out of the 20 cases of impetigo two were found on culture to yield resistant strains of *Staph. aureus*. Both of these cases, reacting in the same way to treatment with the penicillin cream, showed a marked improvement after one week, but relapsed at the end of two weeks, and remained stationary until they were subsequently cured by other methods.

2. *Sensitive Strains*.—Although the *Staph. aureus* and the haemolytic streptococci isolated from 11 of the cases were proved to be penicillin-sensitive, it was found in many of the cases that the penicillin-resistant *Staph. albus* could also be grown from the swab without any apparent effect on the course of the cure. All these 11 were clear in from three days to two weeks, the only remaining evidence of past disease being a slight erythema. It was noticed that none of these cases had a history of more than five weeks.

Two more cases which had been suffering from severe impetigo for 7 and for 40 weeks respectively cleared almost completely, but relapsed in six weeks and eleven weeks. The first subsequently recovered on penicillin, but the second had a residual blepharitis. One case had a secondary infection with *Ps. pyocyanea*, and cleared in two and a half weeks (phenoxetol being highly active against this organism). One case did not return for observation.

In view of the possibility that the length of the history alters the speed and the ease of cure by penicillin, two cases with histories of less than five weeks' duration were given penicillin cream in the usual way for 10 days and 14 days respectively, and then, on the point of complete cure, when they might very well have been discharged, the treatment was stopped. Both immediately relapsed. (They were cleared subsequently, the penicillin being again applied after a lapse of three days. Their cure from the first inception of the treatment took four and six weeks.)

To pursue the investigation further it was planned to make a graph of "depth of organismal invasion of the skin" against "length of cure," and, further, to attempt to correlate these findings with the length of history and the penetrating power of the cream used. Before the experiments could be properly begun one of our helpers was unfortunately taken ill; but our results seemed to indicate that this treatment did not furnish an effective concentration of penicillin in the dermis. Two to three hours elapse before all of this cream has soaked into the skin if the layer applied is 1/16 in. (0.16 cm.) thick, by which time it is thought that the penicillin has lost much of its effectiveness. Sensitive staphylococci in the dermis were certainly unharmed.

Sycosis Barbae

Five patients with sycosis barbae were treated by this method. They had suffered from the disease for periods of five years, two years, a few weeks and ten days respectively. All yielded cultures of penicillin-sensitive staphylococci and streptococci, and all improved very greatly after two weeks' treatment. Over a number of months the improvement was found to fluctuate and reach a stage in which a few pustular follicles persisted in appearance. In spite of this the patients found the treatment more satisfactory than any they had had before by the daily use of the cream after shaving they were able to keep the sycosis very well in check.

Superimposed Infection

This term is used to cover all cases of pyogenic infection following other disease or trauma. Ten such cases have been investigated. They occurred after (1) urea pedis, (2) chronic eczema (2 cases) (1 A.H.F. syndrome), (3) varicose eczema (2 cases), (4) self-inflicted excoriations (2 cases), (5) a diathermy burn; (6) ifumatid lesions on the fingers, and (7) unknown superficial trauma.

(1) This case frequently relapsed developed a lymphadenitis followed by bacteraemia which responded to intramuscular penicillin, and eventually receded from the dermatitis after six weeks, the ulcer remaining as before.

(2) Both patients were clear of the infection in two weeks and neither complained of any increased irritation from the use of the preparation.

(3) Both cases were healed in three weeks.

(4) One of these excoriations had been present for six years except for a brief period, the other was a more generalized and recent crop of spots. With adequate washing and restraint they were healed in four and in two weeks.

(5) This was a burn which had been treated with sulphathiazole ointment and subsequently flavine. The sensitization rash was followed by a large patch of skin infection around the burn. After two weeks the skin was clear and the burn had healed. The rash subsided without further incident.

(6, 7) These patients were clear of infection in a week.

From all these cases penicillin sensitive *Staph. aureus* as isolated, apart from this fact they are not comparable, but serve to illustrate the effectiveness of a low concentration penicillin cream in the treatment of fairly superficial infection.

Otitis Externa and Retro-aural Intertrigo

From all four of these very chronic cases we had excellent results. The shortest history was 10 years, the longest 25, but notwithstanding the consequent fibrosis and the presence of *B. coli* in one ear as a secondary invader, infection disappeared in each case within six weeks, and the cracks were then healed slowly, with the help of silver nitrate. No untoward reactions were observed in this, admittedly small, series of cases. The application of the cream was usually followed by a stinging sensation, but it soon passed off and no visible effects were left.

Conclusions

It is wise to treat all cases without waiting for bacteriological findings (perhaps the phenoxetol and certainly the washing, help).

When impetigo is caused by a penicillin-sensitive organism, and has not been present for more than five weeks, it will heal in from three days to two weeks—usually nearer a week.

To avoid recurrences treatment should be continued in all cases, regardless of the length of the history, until no mark remains on the skin.

In chronic cases, in sycosis barbae and in those few caused by resistant strains, this cream may fail to clear up the disease.

No evidence of a sensitive strain becoming resistant during treatment was found.

Finally, in view of what I believe to be a general lack of faith on the part of civilian doctors in penicillin cream of low concentration, I would emphasize the effectiveness of this very low concentration cream.

I wish to thank Dr J. E. M. Wigley, head of the Skin Department, Charing Cross Hospital, for the original and many other valuable suggestions, as well as for permission to carry out this work, and to express my appreciation of the service of the pathological laboratory and also of the nursing staff in the Skin Department.

Medical Memoranda

Intestinal Hernia between Folds of Broad Ligament

The following case may be of sufficient rarity to be put on record.

CASE HISTORY

Miss A., an A.T.S. private, was admitted to Old Windsor Emergency Hospital from a camp reception station on July 11, 1943, with the following history. Twenty-four hours previously she had developed acute abdominal pain of a colicky type and had had three bouts of vomiting. She also complained of frequency of micturition and headache. The temperature was 100° 8, pulse 92, respirations 20. The tongue was furled. The abdomen was tender and rigid, especially to the right of the umbilicus. The urine was free from acid and albumin. A soap emema had been given but had yielded a very scanty result.

On admission to hospital the temperature was 100°, pulse 92, respirations 25. There were low abdominal tenderness and rigidity and a right-sided paramedian scar resulting from removal of the appendix, with drainage eighteen months previously. On vaginal examination she was tender over the right and posterior fornix especially on palpation of an elastic mass which appeared to lie in the pouch of Douglas. This mass was also felt on rectal examination. Micturition was normally at monthly intervals but the last period had occurred only a week after the previous one had finished. Risk of pregnancy was admitted. During the 48 hours after admission the bowels were opened twice—once spontaneously and once by motions being made in amount.

In view of the history and findings, a tentative diagnosis of ectopic pregnancy was made and laparotomy was performed through the original incision. A little free fluid was present in the peritoneal cavity and the inferior part of the right broad ligament was distended by what proved on investigation to be rather more than a foot of ileum which had passed through a narrow hole in the posterior fold. The hernia was reduced without much difficulty, and the bowel, though very congested, was viable. The rent in the broad ligament was repaired with catgut, and the abdomen closed without drainage. Recovery was uneventful.

It appears that the perforation in the broad ligament may have resulted from the use of a drain after the appendix operation but the exact time when the hernia occurred is problematical.

My thanks are due to Col. Onen P. N. Hard, superintendent of Old Windsor Emergency Hospital for permission to publish this case.

A Case of Penicillin Dermatitis

It is not yet known whether the minor toxic reactions (urticaria, unpleasant taste, headaches, etc.) occasionally occurring after the clinical administration of penicillin are due to the penicillin or to its impurities. Dermatitis following the application of penicillin creams has been thought to be due to the vehicle (lanette wax, etc.). A case of extensive and severe dermatitis after penicillin administration was recently reported in a British officer (Miche and Bailie, 1945). The case described below demonstrates that penicillin itself and not its impurities can be incited as a cause.

CASE HISTORY

A Royal Air Force medical officer, aged 31, was experimentally treated with penicillin capsules (400 units per lozenge) and a throat spray (250 units per c.c.) for a febrile nasopharyngitis and tracheitis. Both spray and lozenges were administered hourly, during the waking hours, for two days, after which all signs and symptoms had subsided.

One week later, T.A.B.C. vaccine, which contains 25% of albumin, was accidentally splashed into both eyes, the acute resulting symptoms being rapidly relieved by copious normal saline irrigation. Fourteen days later there were still signs and symptoms of a mild conjunctivitis, and treatment consisting of zinc sulphate 0.25% drops, junctives, and treatment consisting of an ophthalmologist. No improvement occurring after four days, the treatment was changed to penicillin eye-drops (250 units per c.c.) hourly. Considerable improvement took place within 24 hours, when the patient began to complain of intense itching of the skin over the inferior orbital margins. The next day, penicillin drops having not been used for 48 hours, the conjunctivitis had largely subsided, but the intense irritation continued and a vesico-papular rash appeared. The rash was present over the inferior orbital margins, in a "butterfly" distribution, where the surplus eye-drops had been wiped away by the tribulation, where the surplus eye-drops had been wiped away by the tribulation. All treatment was immediately discontinued. The penicillin solution was found to be still active (more than 200 units per c.c.), and was left at room temperature for subsequent experiment.

The rash subsided without treatment in eight days. It progressed to vesiculation, the vesicles being pin point in size on a papulo-erythematous base. A fine desquamation occurred, the skin finally returning to normal in 14 days. There was no previous history of dermatitis, other rashes, or exposure to the sun. A dermatologist

agreed that the rash may have been a contact dermatitis due to the penicillin solution.

To determine the aetiology of the rash the patient was patch-tested with the original penicillin solution (now found to be completely inactive), a freshly prepared solution of penicillin, and the 0.25% zinc sulphate solution, on the flexor surface of the forearm. This test proved negative. After the rash had completely subsided the patch tests were repeated on the site of the lesions—i.e., immediately below both eyes. In 24 hours the active penicillin solution produced a patch of itching vesico-papular lesions on an erythematous base exactly similar to the original rash; the inactive solution and the zinc sulphate patches were negative.

COMMENT

The inactive penicillin solution can have contained only manufacturing impurities and the breakdown products of penicillin. The fresh solution which produced the positive patch differed only in that penicillin was present. It can legitimately be concluded, therefore, that the aetiological agent in the production of the dermatitis was penicillin and not its impurities. It is probable that sensitivity had been induced in the patient by the course of penicillin 25 days previously. A curious feature is that the conjunctivitis was not aggravated by the dermatitis-producing agent. Winthrop's penicillin, supplied in 100,000-unit ampoules, was used throughout.

The haphazard use of penicillin-containing face powders and toilet applications envisaged in the popular press would appear to be not devoid of risk.

Dermatitis due to Sulphaguanidine

The patient is a private in the R.A.M.C., a member of the hospital staff, aged 41. Before dealing with his present condition it is relevant to consider past events.

He was admitted to hospital on April 11, 1945, suffering from dermatitis of uncertain origin but probably solar, affecting the lower part of the left leg, which ulcerated, this being to some extent due to varicose veins, from which he suffers. Sulphanilamide powder was applied to the ulcer for three successive days, but in view of the lack of response this was stopped and the ulcer eventually healed with simple lotions. There was no generalized eruption at that time. On May 23 the ulcer broke down again, and he was admitted to hospital. He was treated by local saline dressings and parenteral sulphathiazole, of which he received in all 12 g. in three days. On the second day he complained of itching, and on the third day a typical papular eruption was observed on the legs and trunk. The ulcer subsequently healed, and has remained healed.

On July 31, 1945, he was again admitted to hospital, this time suffering from bacillary dysentery. In view of the past history I was chary of giving sulphaguanidine, but as a test I gave him 0.5 g. of the drug in the afternoon of July 31. There was no sign of eruption on the next day and I therefore started him on the normal course of sulphaguanidine—7 g. immediately and 3.5 g. four-hourly. He received 17.5 g. on Aug. 1, and 21 g. on the following day. Towards the end of the second day he noticed a slight erythema of the left leg, and the next morning he presented an almost identical picture to that of the previous sulphathiazole dermatitis. There was a papular eruption covering the anterior and posterior aspects of the trunk, especially the chest, and a similar eruption on the legs, more severe on the left. A serous discharge later exuded from the rash on this leg. The eruption on the back showed a straight line of demarcation from normal skin corresponding to the boundary line of the sunburned area, the untanned area below the belt being free from rash. Similarly the thighs showed few papules, while the legs were severely affected on flexor and extensor surfaces. The face and arms were unaffected, and the arms showed only a small eruption at the flexures of the elbows. The axillae were free. Apart from the serous discharge from the lesion on the left leg, the remainder of the eruption followed a normal course to recovery, using simple lotions. No other drugs were being taken by the patient at the time, nor was there any history of dermatitis following administration of any other drug.

The connexion between the origin and distribution of the dermatitis and the action of sunlight is interesting. Patch tests with sulphanilamide and sulphaguanidine on non-sunburned areas were negative.

BASIL HAIGH, M.B.,
Capt., R.A.M.C.; M.O. i/c British Wing.

Military Hospital, Nira

Five organizations concerned with chiropody and all recognized by the Board of Registration of Medical Auxiliaries—British Association of Chiropodists, Chelsea Chiropodists' Association, Chiropody Practitioners (N.I.Ch.) Ltd., Incorporated Society of Chiropodists, and Northern Chiropodists' Association—have amalgamated to form the Society of Chiropodists Limited. The new organization will also take over the functions of the Chiropody Group Council in relation to the Board of Registration of Medical Auxiliaries, on which body it is directly represented.

Reviews

ALLERGY

Essentials of Allergy. By Leo H. Criepp, M.D. With foreword by Robert A. Cooke, M.D. (Pp. 381 43 illustrations. \$5.00 or 30s.) Philadelphia and London: J. B. Lippincott Company.

This book is one of a series designed to provide concise and effective working manuals for the busy practising physician. It is prefaced by the chairman of the Committee on Education of the American Academy of Allergy, and the author is, among other things, consultant in allergy to the medical service of the U.S. Veterans Administration. The hopes raised by these auspices are not disappointed, for Dr. Criepp has written a compact, well-balanced, and useful account of allergy as it concerns the clinician. In driving a way through the thicket of data and terms which has grown up around anaphylaxis and allergy Criepp has used a bulldozer technique, and it is certain that other pathologists and allergists will not agree with all his definitions and interpretations. Nevertheless, the student will find an extremely clear presentation of the meaning of such words and ideas as atopy, idiosyncrasy, intolerance, and anergy. If he is an intelligent student he will also realize that there are many gaps in our understanding of the allergic diseases. As R. A. Cooke writes in the preface, relatively little is known of the fundamentals of the allergic reactions or the nature of the protective response to present-day methods of immunological treatment, which rests largely on empiricism. It is, perhaps, the only defect of Criepp's book that it gives no explanation of the mechanism of the pollen treatment of hay-fever or the desensitization to liver extract of a patient under treatment for pernicious anaemia. After discussing the fundamental aspects and morbid physiology of allergy Dr. Criepp gives a general account of diagnosis and treatment, and then proceeds to describe the individual manifestations of allergy—hay-fever, bronchial asthma, nasal allergy, skin allergy, serum allergy, bacterial allergy, fungus-allergy, physical allergy, and a miscellaneous group. Each chapter has a helpful summary, and there are short case-histories followed by lists of teaching points. The book is indeed a most successful teaching manual. Looking at it from a broader scientific aspect, however, the general physician or pathologist may wonder whether the specialist in allergy is perhaps not too preoccupied with the handling of the familial allergies or atopy, as he calls them. These are characterized by two features. The first is an abnormal tendency to produce *reagins*—that is, to become sensitive—to common substances in the environment. The second is the possession of a shock organ, usually the respiratory tract or the skin. The detection of the substances which may provoke asthma or rhinorrhoea in susceptible people has perhaps precluded us from thinking hard enough about the acquired or intrinsic asthmas and about the reason for the localization of symptoms. The identification and listing of allergens must obviously continue, and we are only just realizing the allergic potentialities of sulphonamides, thiouracil, penicillin, and a host of other non-protein compounds used in medicine and industry. However, just because the number and variety of allergens are almost unlimited it will be profitable now to think a little harder about what makes a shock organ such, and why the reaction is sometimes so exquisitely particularized, as in the response of the platelets in the drug purpuras. There are, indeed, few fields of clinical science in which a greater harvest of useful knowledge waits to be gathered than in the allergic diseases.

BLUE-PRINT FOR THE NATION

Post-War Britain. Edited by Sir James Marchant, K.B.E., LL.D. (Pp. 255. 12s. 6d. net.) London: Eyre and Spottiswoode.

Sir James Marchant has assembled eleven leading authorities, each of whom discusses the phase of post-war reconstruction in which he is an expert. Lord Horder writes about the future health of the nation. It is difficult to avoid platitudes in writing about health, but Lord Horder's style is always refreshing and he salts his essay with epigrams. Thus he suggests that one way of attaining health is to be "really convinced that it is better being well than ill"—a precept which needs to be placed in front of a good many people. He also touches on the contribution to health which is to be made by the State. Evidently

his essay was written not only before the recent change of Government but before the Willink negotiations. He says that the White Paper is to be welcomed as a compromise between the present unsatisfactory state of our health services and a whole-time State service for all doctors though the White Paper requires certain adjustments to make it more acceptable. Of these adjustments he notes three: freedom of private practice, continuation of contributory scheme and a fuller and more direct representation of the profession on controlling bodies. Sir John Orr writes on the future of the future, and describes the Hot Springs Conference of May, 1943 as the starting-point of a new era in which science will be applied directly with all its powers to supply the things man needs. Once get that direct application of science started and the road to the age of plenty, while it may be a long one will be undeviating. Sir Ernest Simon writes with equal authority on his own subject of housing and goes into much useful detail as to costs and subsidies rents and rates. Other experts write on agriculture, plastics, coal, iron and steel and electrification. It is rather a relief to find no mention of atomic energy in a volume on the lay out of the country. But this volume, as its cover proclaims, is "a blueprint for our national life" it leaves out as many elements as it includes. There is no section on town and country planning or civil engineering or local government and services, nothing about education or recreation, or the culture of mind and spirit. It presents so far as it goes, a very competent and orderly landscape, but rather a truncated one, and not much sky.

SURGICAL TREATMENT OF PEPTIC ULCER

Duodenal and Jejunal Peptic Ulcer. Text and Pictures. By Dr. R. Nissen. M.D. (Pp. 143, illustrated 215) London W. J. B. Lippincott 1945

The results of partial gastrectomy in the treatment of peptic ulceration are usually acknowledged to be more satisfactory than those of other surgical methods of treatment except perhaps in a very restricted number of cases. The main objection to this operation is the mortality associated with its performance, which, although now considerably reduced still remains well above that of simpler procedures. Analysis shows that this mortality is mainly due to two complications, collapse and infection of the lungs being the chief hazard, with leakage from the duodenal stump coming second.

Reliable closure of the duodenum must therefore be considered one of the most important technical details of the operation. A new book, *Duodenal and Jejunal Peptic Ulcer*, by R. Nissen of Brooklyn, despite its rather deceptive title, is devoted largely to the practical means by which this may be achieved. We must confess that we wondered whether such a small, if important, detail warranted the production of a whole book on the subject, for a properly trained surgeon should be competent to devise means of dealing adequately with difficult circumstances as they arise on the operating table, but the author, anticipating this criticism, justifies his contribution by the statement "In about 50% of all cases in which surgical intervention for ulcer is indicated, the procedures herein described are applicable. There is a good discussion of the pros and cons of the prepyloric division of the stomach, which reveals the author strongly in favour of section of the duodenum beyond the ulcer, although the floor of the ulcer may remain if it has penetrated through into the surroundings and especially the pancreas. This is the general conclusion reached by gastroenterologists in this country. In brief, the author's method of dealing with a difficult duodenal stump is to leave sufficient anterior wall (the ulcer being usually posterior) to turn over and unite with the freed posterior wall immediately beyond the floor of the ulcer, afterwards burying this within the capsule of the pancreas. It is a method often used *secundum artem* by surgeons well versed in the technique of gastric resection. For exceptional cases where the anterior wall is deficient other procedures, such as a duodeno jejunal anastomosis are advocated.

The second half of the book deals with anastomotic ulcers and gastro-jejuno colic fistula. In the latter condition the author correctly as we believe, describes Lahey's two stage resection of colon, stomach, jejunum, and duodenum, with ileo-colostomy, as being unnecessarily severe and physiologically undesirable.

The book is admirably illustrated and well produced, it has a foreword by Owen Wangenstein.

Notes on Books

Ophthalmia Neonatorum. The Problem after Thirty Years of Sanitary Notification and Sixty Years of Crede Prophylaxis. By ARNOLD SORSBY, M.D., F.R.C.S., as published by Harmsa Hamill on Medical Books at 75 6d. This is the first monograph from the Institute of Ophthalmology. It consists of a very useful collection of material which has mostly been published already, together with conclusions drawn therefrom. It will form a useful reference book for those who are seeking statistical data, since 31 of the 64 pages are occupied by tables or graphs. There are a foreword by Sir Alan D. Davy and an exhaustive bibliography. It is surprising that no reference is made to the late M. S. Mayou (except in the bibliography) to whom is due the original organization of White Oak Hospital, St. Paul, and St. Margaret's Hospital, Kenilworth, and whose work in that connexion was recognized by all ophthalmologists.

Internal Medicine edited by JOHN H. MESSER (HARRIS LIPPINCOTT 50s.) is obviously popular in the United States, as is shown by the appearance of a fourth edition. In size and scope it lies about half way between "Conveyance and Inner" though like many text books of medicine, it is showing a tendency to grow in size. The third edition was 140 pages longer than the second and the fourth is 200 pages longer than the third. As the student's time is not increased, and as it is undesirable to lengthen the clinical course, it looks as if the time has come when a new approach should be made to the problem of writing textbooks for students. Probably on the lines of general pathology and special pathology. Wartime advances in medicine have been included, though it is too early for them to have been properly assimilated. Thus quinine is preferred to atabrine in the prophylaxis of malaria and penicillin is recommended in the treatment of acral leucoderma.

The Information Division of the European Regional Office of UNRRA issues a periodical *Review of the Month* from 11, Portland Place, London, W.1. The latest number (for October-November, 1945) records the second anniversary of the foundation of UNRRA and gives news of the work of the missions in various European countries.

Preparations and Appliances

A SIMPLE "PROPRAY" FOR USE IN GENERAL ANAESTHESIA

Dr. BARNET SOLCOW'S (London, N.V. 8) writes

Every anaesthetist has faced the problem of the closed mouth in light anaesthesia. All degrees from gentle closure to extreme masseteric spasm, have presented themselves from time to time.

This simple divided propway has been found useful in general anaesthesia of all types. It is inserted before induction, is quite comfortable, and never causes gagging or unpleasantness to the patient. It gives ample access and allows easy control of the tongue by the forefinger, spatula, or closed tongue. It can be used as a hooked spatula. The blade of a laryngoscope can be inserted in light anaesthesia without the necessity for force opening the mouth. If an oral endotracheal tube is passed this can be slipped through the slot and if necessary tied to the propway, thus protecting the tube from the patient's bite. A flat type pharyngeal metal or rubber airway can be inserted and supported similarly. Finally the propway can be used with the open side towards either angle of the mouth.

I am indebted to Private T. Smith R.A.M.C., for his help in the design of this device. It is obtainable from Medical and Industrial Equipment Ltd., 12, New Cavendish Street, W.1.

HORMONE PRODUCTS

The Organon Laboratories Ltd. offer for sale "cortrophin," a preparation of the anterior pituitary hormone which promotes growth of the cortical cells of the suprarenal gland. It is recommended for use in Simmonds's disease (pituitary cachexia), anorexia nervosa, and for the asthenia and hypotension of convalescence. They also offer "neo hembreol (M)," which is methyl testosterone, this is recommended for various purposes: (a) to protect the weight curve of premature infants, (b) to deflate the colon in cases of Hirschsprung's disease, (c) in nocturnal enuresis, etc. A third preparation is "menformin" in the form of a standardized oestrogenic cream for local application to the skin of the breasts and the vulva.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 12 1946

CHILD HEALTH IN BIRMINGHAM

The gift by the Nuffield Foundation of £10,000 a year to the University of London in 1944 to found a professorship and institute of child health has inspired Birmingham to try again—it had tried unsuccessfully twice before, once in 1929 and again in the early part of the war—to set up an organization on similar lines. A scheme for an Institute of Child Health has now received the approval of the Birmingham City Council, and, although Birmingham cannot be said to be the pioneer in this respect, it is hoped that its scheme will present a model of completeness, with all the various services which have child health as their object properly integrated in a way which would not be possible in a smaller city owing to lack of provision, nor in London owing to its vast extent and the variety of its resources. All the preventive and curative agencies, including research and education, will be directed to dealing with disease in children and to raising the standard of child health in the West Midlands area.

To ensure the success of any such scheme a partnership of three is necessary—the children's hospital, the local authority, and the university department. Birmingham is fortunate in commanding for this project the sympathy of all three. Its Children's Hospital—the King Edward VII Memorial—is one of the best general hospitals in the Provinces, with a high reputation as a research centre. It is quite near to the centre of the city, with modern buildings, a good site, a large out-patient department, a fully organized pathological laboratory, a new infants' block carefully planned and not yet in proper use, and a medical staff with a full range of physicians and surgeons in charge of general and special departments who are also engaged in private consulting practice. It has two annexes at Malvern for the treatment of certain clinical types of long-stay patients, and one at Northfield for use as a continuation hospital for infants and nursing mothers.

The second partner, the City Council, had already raised its child health services to a high excellence; its provision for the care of premature infants need only be mentioned. The Education Committee has expressed its desire to be in the scheme at its inception, and it was actually the Maternity and Child Welfare Subcommittee, in warmly supporting new proposals which were broached by the chairman and late house governor of the Children's Hospital, which led to the matter being taken up afresh. On the municipal side the scheme will include the present maternity and child welfare service of the Corporation, the school medical service, and that part of the tuberculosis service which is concerned with children. Presumably the 300 beds for children at the Dudley Road and Selly Oak

municipal hospitals will be linked with the scheme. It is expected that other local authorities will participate in due time; as it is, 30% of the patients in the Children's Hospital come from outside Birmingham.

A co-ordinating role will be taken by the third partner, the University, where the Professor of Children's Diseases is Dr. Leonard G. Parsons, well known not only as a paediatrician but as a teacher and administrator, who has obviously taken a leading part in the shaping of this enterprise. When the scheme is more advanced no doubt his title or that of his successor will be changed to that of Professor of Child Health, to emphasize the more positive side which this whole movement signifies. The preventive and sociological aspects will be kept in full view. Each of the three partners will be able to make its own contribution to the study of the social conditions under which children in Birmingham and in the Black Country live—the Children's Hospital through its almoners, the local authority through its health visitors, and the University through its Department of Social Medicine.

It is hoped eventually to build an Institute of Child Health adjacent to the Children's Hospital. For the present, however, much of the work will be housed at the Carnegie Institute, which was originally designed as a model child welfare centre. It is anticipated that the management of the scheme will be in the hands of a council representative of all three partners, the Children's Hospital being represented by members of its medical committee and lay board; the local authority by its medical officer of health and other medical officers and members of the committees concerned; the University by its Vice-Chancellor, other members of its Council, and its Professors of Child Health, Obstetrics and Gynaecology, and Social Medicine. Certain suggestions, which cannot yet be complete, have been made for staffing. The present holder of the Chair of Children's Diseases is a part-time officer; his successor would devote the whole of his time to this post; he would also be consultant to the child health services of the city, physician to the Children's Hospital, and visitor to the municipal Babies' Hospital at Cranwell Hall. With him would be two University Readers, one of whom would be responsible for the organization of undergraduate and postgraduate training in the preventive aspects of child health, and a lecturer in child welfare. All the members of the honorary staff of the hospital would be clinical lecturers in the medical school, and would be available for consultations at the child welfare centre at the Carnegie Institute. With each of the four or five physicians of the hospital, who would also be engaged in private practice, there would be associated a clinical assistant selected, like the lecturer on child welfare, from among the whole-time medical officers of the local authority. Each of these clinical assistants would act as medical officer at certain stipulated times in the wards and out-patient department. It is suggested that there should be three medical units in the hospital, each consisting of physician, assistant physician, clinical assistant, and house-physician. A fourth registrar would be attached to the infants' block, the pathologist, or the research department. The service, when it is fully established, is expected to cost from £15,000

to £18,000 a year, and this will be borne about equally between the three partners.

The Children's Hospital at present has 248 beds in use, with about 8,000 in-patients and 19,000 out-patients a year. The survivors who were appointed by the Ministry of Health to survey the hospital facilities of the West Midlands area—Mr J. B. Hunter, Dr R. Veitch Clark, and Sir Ernest Hart—reported that the beds available for children in Birmingham are not sufficient for the city and for the specialized orthopaedic service which will have to be provided in Birmingham for the West Midlands area. They point out the importance of beds because children's diseases do not lend themselves to out-patientists. One of their recommendations is that the Children's Hospital should be brought up to the highest and maximum desirable on the site, thereby affording better facilities for the grouping of cases. Another suggestion of theirs is that the general hospitals, municipal and voluntary, should each have an adequate paediatric department directed by a paediatrician who should preferably be on the staff of the Children's Hospital. They even go further in anticipating the new scheme by urging increased integration of the activities of the Children's Hospital and the Hospital Centre with the maternity and child welfare and school medical service of the Corporation. Apart from what the scheme promises for the health of the children of the West Midlands and the example which it will set to other centres, it provides an admirable instance of co-operation between municipal and voluntary enterprise in a most obvious and practical field.

SOLUBILITY OF SULPHONAMIDES

It has long been recognized that the physical properties of drugs have a profound influence on their clinical use and effectiveness, such properties as solubility in water or fat solvents, and acidic or basic character, influence not only the ways in which drugs can be administered but also the ease of their absorption, their distribution throughout the tissues, and their potency in any given situation. In recent years attempts have been increasingly made to put these effects upon a quantitative basis, and the article by Prof. H. A. Krebs and Dr J. C. Speakman in this issue is an important contribution to studies of this kind. They are concerned with the relation between the solubility and the acidic character of sulphonamides.

The sulphonamides are sparingly soluble substances with both acidic and basic properties but within the physiological range of pH the acidic properties appear to be predominant. Like most insoluble organic acids, sulphonamides form soluble salts and are therefore soluble in alkaline solutions. When the salt of an organic acid is dissolved in water an equilibrium is set up between the anions of the salt and the un-ionized acid molecules, and the proportion of un-ionized molecules will depend upon the strength of the acid and upon the pH of the solution, the weaker the acid the greater the proportion of un-ionized molecules at a given pH. The number of un-ionized molecules is, however, limited by their solubility, so that at any given pH the total solubility (un-ionized molecules

plus anions) will depend upon the strength of the acid. The strength of an acid is usually measured by its acid dissociation constant K_a or by its negative logarithm pK_a . A knowledge of K_a enables us to calculate the proportions of ionized and un-ionized molecules, and, consequently, if we know the solubility of the un-ionized molecules we can calculate the total solubility at any given pH. Krebs and Speakman describe a method of measuring both K_a and the solubility of the un-ionized molecules, which they designate S^0 , by two measurements of total solubility at two different pH values. Their results demonstrate that the sulphonamides are much more soluble in buffered solutions at pH 7.4—the approximate pH of plasma—than in simple aqueous solution, and provide a rational explanation of this greater solubility. The attainment of an effective bacteriostatic concentration in the tissues is thus seen to be at least partly dependent on the strength of the sulphonamides as acids. The question which naturally leaps to the mind is whether the anion or the un-ionized molecule is the effective bacteriostatic agent. No certain answer can as yet be given to this question, but its importance can be illustrated by example of other drugs.

Because a drug administered as a neutral salt it does not necessarily follow that the pharmacologically active agent is the ion of the salt. Thus it is not the mandelate anion which is bacteriostatic in urine but un-ionized mandelic acid and hence the need for maintaining an acid urine when the drug is being used. Similarly, it is not the cation of a local anaesthetic salt which possesses anaesthetizing properties for sensory nerves, but the un-ionized base. A good local anaesthetic must then be a sufficiently weak base to produce an adequate proportion of un-ionized molecules of base at the pH of the tissues, at the same time it must not be so weak a base that the concentration of un-ionized molecules at the pH of the tissues exceeds the solubility of the base; otherwise the local anaesthetic will be precipitated. The good local anaesthetic requires an appropriate balance of these two properties—basic strength and solubility—and it may well be that the bacteriostatic properties of sulphonamides also depend on a balance of the two properties—acidic strength and solubility in water. The solution of this problem would provide a valuable guide not only to the synthesis of new drugs of the sulphonamide type but also to the use of sulphonamides in particular physiological situations.

PENICILLIN IN ACUTE OSTEOMYELITIS

Sir Howard and Lady Florey,¹ reporting their first therapeutic trial of penicillin in osteomyelitis, prophesied in 1943 that a time might come when that disease, treated early and intensively with penicillin, would not require surgical intervention. Recent papers by Altmeier and Helmsworth² and by McAdam,³ suggest that the Floreys' early prophecy is close to fulfilment.

The more important conclusions reached in the two papers are in close agreement, and may be summarized

¹ *Lancet* 1943, 1, 387.

² *Surg. Gynec. Obstet.*, 1945, 81, 138.

³ *Brit. J. Surg.*, 1945, 33, 167.

briefly. (1) A suitable daily dose is 100,000 Oxford units administered by continuous intramuscular drip or by three-hourly injections. (2) Treatment should be continued for at least two weeks, or until three specimens of pus obtained by an intrametaphysial needle are sterile (McAdam). (3) Ancillary surgical measures should be limited to the immobilization of the affected limb, the incision of abscesses, the late removal of large sequestra, and the insertion on occasion of a sternal-puncture needle into the metaphysial focus. Marrow drainage, performed in five of McAdam's patients, and these not the most severely affected, was followed in at least two cases by wide sequestration and persistent sinuses. (4) Penicillin therapy should be established for twenty-four hours before any surgical procedure, even the opening of an abscess, is undertaken. (5) With adequate penicillin administration an initially positive blood culture becomes negative after three days or so. (6) The patient's general condition improves, but only after a few days' treatment. (7) The initial temperature, continuing high for a few days, falls gradually to normal after a week or more. (8) Metastatic foci present when the patient is first seen respond well to suitable surgical procedures during penicillin administration; new metastatic foci are not likely to develop once treatment is begun.

The radiological record of the behaviour of an infected bone under the influence of penicillin is interesting. The characteristic feature is a mottled demineralization, which proceeds to a maximum translucency weeks, or months, after all infection has subsided, and which is ascribed to a post-infective absorption of lamellae killed during the infective period. Quite large sequestra sometimes fade gradually, and in both papers an analogy is drawn between this phenomenon and the absorption of sterile bone-chips transplanted to fill a defect. In both circumstances demolition must be complete before reconstruction can proceed.

McAdam has inserted a sternal-puncture needle directly into the infected metaphysis, as suggested by Aird.⁴ Pus can be withdrawn immediately to decrease tension in the metaphysial abscess, and to permit precise diagnosis and an estimation of the penicillin-sensitivity of the responsible organism. If the needle is left in place, and if specimens of pus are withdrawn at intervals, the time of sterilization, when penicillin administration can safely be discontinued, is precisely known. Further, the needle offers for continuous penicillin administration an alternative (intrametaphysial) route, by which can be attained not only a high blood level of penicillin but also a high local concentration, which may be particularly valuable if an adjacent joint—the hip, for example—has been directly infected. Only one of McAdam's 40 patients died, from an infection by a partially penicillin-resistant *Staph. aureus*. Altemeier and Helmsworth, in 34 cases, had also one fatality—a case of severe haematogenous osteomyelitis of the tibia neglected for fourteen days; death took place seventeen hours after admission to hospital. The fatality rate of osteomyelitis is a notoriously fallacious criterion of the efficacy of a form of treatment, so much does the disease vary in severity from year to year and from lustrum to lustrum in an irregular epidemiological curve. Yet a fatality rate of 2.8% in the combined series of 74 cases, of which more than half had positive blood cultures, supports McAdam's conclusion that "recovery can be anticipated in every patient with acute haematogenous osteomyelitis treated with penicillin, provided that the infecting organism is penicillin-sensitive, and the patient is not *in extremis* when first seen."

THE LEAGUE OF NATIONS IN THE WAR

The report on the work of the League during the war¹ by the acting Secretary-General (Mr. Seán Lester) is to be submitted to the League of Nations Assembly which will be convoked in 1946, presumably for the last time. It is a printed document of 167 pages. The first chapters describe the non-political activities which were carried on in Geneva, in America, and in London during the war. Such activities covered various fields: economic, financial, communications and transit, health (14 pages), control of the drug traffic (32 pages), social questions, legal questions, etc. Other chapters deal with internal matters, such as budget and staff. The report is likely to be the last comprehensive statement on activities submitted by the acting Secretary-General before the winding-up of the League. The introduction gives the reasons why activities have been maintained, noting especially their usefulness with regard to post-war reconstruction. The problems connected with a possible transfer to the United Nations are also mentioned. They will be fully reported upon after the reception of proposals from the United Nations and the contemplated preliminary discussions with the Supervisory Commission of the League. The introduction also tries to assess the value of the first experiment in world organization. While non-political activities have survived the war, and may to a great extent be taken over by the new organization, the political provisions of the Covenant were left in abeyance and have now been suspended. One of the main lessons of the past is that the success of the fresh experiment will depend less on machinery than on a new spirit in peoples and their leaders. "The powers of destruction which would be let loose in a new conflict do not permit the envisaging of a possible failure."

STATISTICS AND THE M.O.H.

Medical officers of health, to judge from their annual reports, differ widely in the use they make of statistics. Some of them dismiss the vital and morbidity statistics of their area with a mention; others give long tables of mortality rates and notifications of cases and compare the year under review in all these respects with many previous years. Carlyle put into the mouth of an anonymous statesman the remark—which has been quoted most unscrupulously in every sort of argument ever since—that figures can be made to mean anything. An outsider attending, let us say, the meetings of the Royal Statistical Society, more particularly its recently revived Research Section, would not subscribe to that easy judgment, but he would agree that statistics rarely carry the significance which a superficial reading of them suggests.

It is perhaps because there are several ways of looking at statistics that we have two successive presidents of the Society of Medical Officers of Health—the president for the current year, Dr. J. Johnstone Jarvis, and his immediate predecessor, Prof. R. M. F. Picken—in their respective presidential addresses speaking of the statistical method in contradictory terms. Prof. Picken reminded us that earlier medical officers of health made full, if not always very skilled, use of statistical inquiry, and thereby did much to awaken the minds of the lay public and of other members of the profession to public health problems. It might be, he said, that nowadays expert statisticians had raised so many statistical bogies that the medical officer of health was being frightened off this field. He also referred to the possibility of a new system of collecting morbidity statistics, showing, for example, in an area, what diseases and dis-

⁴ *Proc. roy. Soc. Med.*, 1945, 38, 569.

¹ George Allen and Unwin, Ltd., 40, Museum Street, W.C.1. Price 7s.

abilities affected different age, sex, occupational, and social groups, and he suggested "there was scope for specializing, as did our fathers in public health with much less material, in the interpretation of statistical information. On the other hand, Dr. Johnston Jones confessed himself disturbed by the suggestion that in the new order one of the main preoccupations of the medical officer of health will be demography. He had always contended that to obtain the maximum advantage from a statistical evaluation of medical material the services of an expert statistician were required, and that very few medical officers could claim to be experts in this field. He agreed that the medical officer should compile cards in statistics for his area, but statistics "can be time-consuming and unless he is prepared to let other work go by default and to sacrifice some of his leisure the average medical officer of health simply has not the time to devote to them."

Between these divergent views it is difficult for those who are neither in public health nor in statistics to express an opinion. No one would suggest that the medical officer of health should become a mechanical tabulator but surely his main preoccupation is the study of man in the mass and not man as an individual, and to prosecute this study efficiently he must do it with the instrument of statistics. Knowledge so gained should enable a medical officer to make a fully delineated "map" of his area which would, for example, indicate the need for special precautions at certain points and for particular concentrations of effort and enable the machinery of public health to be used more effectively, more economically, and with less likelihood of error. To quote a wiser remark from Carlile: "The odious man looks at statistics, not to get knowledge but to save himself from having ignorance foisted upon him." It is not merely technical knowledge and mathematical skill which are required in handling statistics: it is a quality which Prof. Major Greenwood, in a recent speech at the Royal Statistical Society, described as something akin to what in the medical profession is called clinical instinct: perhaps it is a flair, or, less mysteriously, just the absence of a fear of figures, combined, in the case of medical statistics, with medical knowledge.

THE TAVISTOCK CLINIC

The Tavistock Clinic (the Institute of Medical Psychology) was founded by Dr. Crichton-Miller and a small group of colleagues in 1920, largely as a result of experiences of the 1914-18 war. By 1939 the Clinic was treating psychologically both adults and children from all parts of the British Isles. It was also undertaking postgraduate medical education in the diagnosis and treatment of neurosis, as well as research projects aided by grants from the Rockefeller Foundation, the Halley Stewart Trust, and other bodies. On Dec. 11, after a wartime migration to Westfield College, Hampstead, and the bomb destruction of its old premises in Bloomsbury, the Clinic reopened at No. 2, Beaumont Street, Marblebone, a large house which was formerly a nursing home. Lord Alness the chairman, told those assembled for the house-warming, which coincided with the twenty-fifth birthday of the Clinic, that before the war it had provided lecture courses for upwards of 2,000 medical men and women and a thorough two years' training in this field for about 100. In 1939 a medical staff of 90, largely unpaid, provided 26,000 hours of treatment. Later about 40 of the staff were called up, but the work had continued. The problems to which they had to address themselves now included post-war breakdown, child delinquency, training for doctors in these subjects, and assistance to industry in the field of psychological medicine.

The Tavistock Clinic confines itself to the treatment of cases of neurosis. It tries not to overlap the work of other institutions dealing with more serious breakdown. It is especially concerned with cases of irrational anxiety, hysterical conditions, obsessions and conduct disorders. Every patient obtains on the average 26 hours of a doctor's time. A careful follow-up of pre-war patients has shown that 50% of adults and 70% of children have maintained their cure. The number of people needing treatment now is not fewer than it was 25 years ago, and there is greater awareness of the need and readiness to seek it.

Dr. J. R. Rees, medical director and one of the original eight, who has worked there during the whole of the 25 years, pointed out that over 30% of all the medical discharges from the Army, to which he was consulting psychiatrist, had been on psychiatric grounds, and that figure was paralleled by the discharge rates in the other two Services, and rather exceeded by the figures for some of our Allies. The great majority of these were not catastrophic breakdowns but cases of neurotic disturbance or difficulty. With so many potential patients the Clinic would have to try new methods. Some experiments in group rather than individual treatment had already been started. Another important task was the prevention of breakdown.

General Sir Ronald Adam, Adjutant General since 1941, spoke on selection methods in the Army. Selection procedure—the finding of the man for the job—had done much for morale. The men who, after training, might be unsuitable for front-line work had a psychological interview, and on the results of that interview were placed in other jobs. Men who had qualities of leadership were earmarked at the outset. In problems of morale, particularly in the Far East, psychiatrists were constantly used by commanders at all levels. Another task in which psychiatrists and psychologists had done great work was in civil resettlement units, which had proved very successful. He thought that post-war industry could learn something from the methods pursued in the Army. The Civil Service both at home and in India, were using adaptation of Army methods for personnel selection, and there were other aspects of Army experience, such as the discussion group idea, which should have their counterpart in industry.

As to the future of the Tavistock Clinic, Lord Alness indicated that this must be measured in terms of finance. To function properly the Clinic requires an income of at least £10,000 a year. Only £3,000 of this can be expected to come from patients.

THE HALF-YEARLY INDEXES

The half-yearly indexes to Vol. I of the *Journal* and the *Supplement* for 1945 have been printed. They will, however, not be issued with all copies of the *Journal* but only to those readers who ask for them. Any member or subscriber who wishes to have one or both of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Accountant, B.M.A. House, Tavistock Square, London, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

Kodak Ltd. have presented to the Royal Society of Medicine the Kodak Medical Film Library. The library service for these films is now operated by the Society, and all correspondence should be addressed to the Film Librarian, Royal Society of Medicine, 1, Wimpole Street, London W.1. This library, which was first made available to the medical profession by Kodak Ltd. in the year 1930, has served a useful purpose in establishing the value of the motion picture in medicine.

EFFECT ON TROOPS OF THE "V" WEAPON BOMBARDMENT OF ANTWERP

BY

A. G. FREEMAN, M.R.C.S., L.R.C.P.
Capt., R.A.M.C.

As a medical officer in charge of a medical inspection room in Antwerp since Sept., 1944, I have had an opportunity of studying the effects of flying bombs and rockets on military personnel stationed in my area. My report must necessarily be incomplete, as an efficient follow-up has been wellnigh impossible, owing to the large turnover of troops and to the speedy evacuation of those requiring hospital treatment. I am therefore confining myself to the presenting symptoms of "exhaustion" and to a few general observations.

Details of the Report

A statement issued by the H.Q. in this area announced that between Oct. 7, 1944, and March 30, 1945 (175 days) the total fall of shot reported was 5,960 (4,248 "V 1" and 1,712 "V 2"). Of these, 3,709 (2,248 "V 1" and 1,261 "V 2") fell on Greater Antwerp and arrondissement—an area of 391 sq. miles (1,012.69 sq. km.)—and 1,214 on Greater Antwerp itself—an area of 65 sq. miles (168.35 sq. km.). All troops attending this M.I. room were stationed in the Greater Antwerp area, where an average of 18.67 bombs fell into the square mile (2.59 sq. km.).

My report covers a period of four months from Nov. 19, 1944, to March 10, 1945, when the attack on Antwerp was at its height. During this time 1,780 new patients reported to the M.I. room. This represents an average daily sick rate of 6.4 per 1,000 men, and of these, 63 (i.e., 3.5% of total sick—a daily rate of only 0.22 per 1,000 men) were diagnosed as cases of "exhaustion." During this period this M.I. room was responsible for some 5,000 line-of-communication troops, and on the average these units remained here for only two or three months before being replaced by fresh troops. Ten units, however totalling just over 1,000 men, were in my area for the whole period of four months, and they produced 60.3% (38 out of 63) of the cases of "exhaustion," while the remaining 25 cases came from a total strength of over 4,000.

Classification of Cases

These cases could be classified into two main types, depending on their presenting symptoms.

Type 1 consisted of those who showed all the classical signs and symptoms of fear, ranging from mild cases to extremes of panic. The patient, on first reporting sick, would admit at once to being afraid. He may have taken several days or even weeks to make up his mind to report sick—until the matter was settled, once and for all, by some particular incident or experience. Once decided, however, he made no attempt to conceal or minimize his feelings; on the contrary, the trouble was often obvious from his speech and general behaviour before he had completed his "history." He expressed his fears in a variety of ways, but he never had any doubt as to their cause.

11 degrees of severity were encountered. The patient complained merely of not feeling quite himself or of feeling run down and continually tired, or even tendered a direct request for sleep on the ground floor. He sometimes complained of sweating, cold shivers, trembling, twitches, loss of appetite, and palpitations, and said that he had lost all interest in his work and ability to perform it efficiently. He no longer enjoyed his previous pursuits of leisure hours, such as reading, writing home, or visiting the local cinemas and cafés, and instead became moody and irritable, and preferred his own company. He found the nights worse than the days, and remained awake, restless and on edge, waiting for the least sound of distant gunfire or the approaching bomb. If sleep, once achieved, was disturbed in the early hours, he lay awake for the rest of the night. On hearing a bomb approaching he either found himself

unable to move, cowering under the bedclothes, or rushed wildly about the room, panting for breath or shouting till he "took cover" in a corner or lay exhausted on the floor. He often remained in such a state long after the danger had passed. It was noted that if an "incident" occurred while being examined he became pale, trembled, sweated, and exhibited tachycardia.

Type 2 consisted of those who complained of some specific symptom or symptom-complex such as headache, dyspepsia, insomnia, or loss of weight, without any obvious manifestation of fear. Some information as to the underlying cause of the complaint could normally be elucidated from their "history," or, more easily, from a friend, but it was usually not possible to pronounce a definite diagnosis till physical and, in some cases, special examination had excluded the possibility of any organic basis. In contrast to *Type 1*, fear was never the predominant manifestation, and, moreover, the patient would not readily admit that he was afraid.

Case Reports

Case 1.—Driver A. Stated age, 45; true age, 49. Reported sick in Feb., 1945, complaining of severe frontal and occipital headaches, tiredness, pain in the back, and loss of appetite. He said that in the last four days he had taken 100 aspirin tablets to relieve his headache (new bottle of aspirins found on him), and that he was not worried unduly by the flying bombs. On examination it was found that he had scabies; nothing else abnormal. Was seen under escort as charged with absence without leave. Information gathered from an N.C.O. in his company was that he was extremely nervous and rushed about when he heard a flying-bomb approaching. Known throughout his unit as "Bombhappy."

Case 2.—Lieut. B., aged 29. Served with the A.E.F. in 1940. Evacuated from France in transport ship which was dive-bombed and sunk with heavy loss of life. Rescued from the sea after swimming about for some time. Later served in England during the air raids. After three months' stay in Antwerp he was visited in his quarters, where he complained of bouts of diarrhoea, weakness, loss of appetite, tiredness, and generally feeling "out of sorts." Admitted that he slept very little at night owing to a state of tension. On examination his temperature was subnormal and pulse rapid; nothing else abnormal. Had never mentioned his symptoms to his fellow officers, though they had noticed him becoming very quiet and increasingly nervous. Admitted to hospital, where he was treated with prolonged narcosis. Now back on duty in B.L.A.

Headache, the commonest of all the symptoms, was the primary one in 14 cases. The usual site was occipital, followed by temporal, frontal boring through to the occiput, and purely frontal (bilateral or unilateral), in that order. The headaches were constant throughout the day, and were unaccompanied by visual disturbances, nausea, or vomiting. They were only partly relieved—if at all—by aspirin or codeine tablets, and were aggravated by noise and worry. Some of these cases were sent as hospital out-patients, with the tentative diagnosis of sinusitis or eye-strain, producing negative results. In the main, however, the site and nature of the headaches and the variety of accompanying symptoms made the diagnosis generally clear.

The morning sick parades were seldom completed without one or two cases of dyspepsia, and its differential diagnosis at any time presents difficulties. Only those cases (8 in number) associated with obvious psychological abnormalities are thus included in this report. Epigastric discomfort, rather than actual pain, was the usual symptom; it had no definite relation to the quality or quantity of food taken, and occurred at varying times after meals. The patient was free from it only for brief periods throughout the day. Some complained of nausea but none of vomiting. Loss of appetite, loss of weight, insomnia, backache, palpitations, sweating, localized pain over the heart, and shortness of breath formed the majority of the remaining symptoms. There were also 2 cases of enuresis, 1 of masturbation, and 1 showing marked symptoms of depression and persecutory delusions.

Previous experience of heavy air raids or front-line service certainly seemed to give rise to earlier and severer symptoms (see *Case 2*). This was especially noticeable in the case of three men who, after being admitted to hospital from Normandy and Holland as psychiatric casualties, had been discharged and posted to units stationed in Antwerp. After a stay here of only a few days all three reported sick with a recurrence of their original symptoms, and required evacuation.

* The term "exhaustion" is used in this report to cover all cases showing anxiety or other psychiatric symptoms, whether they needed admission to hospital or not (vide "Memoranda of Medicine" 3, H.Q., 21 Army Group, May 8, 1944). It does not include casualties from bomb incidents.

Disposal and Treatment

The disposal and treatment of these cases were as follows: 19 out of 63 (30.1%) required evacuation to hospital, some others were admitted as out-patients, while treatment for all the milder cases was carried out in unit lines, and consisted of reassurance and if necessary rest and sedation. For this purpose barbitone soluble (10 gr. (0.65 g.) nightly or 5 to 10 gr. (0.32 to 0.65 g.) three times a day) was given. In most cases this was sufficient, but if no improvement was noticed after a few days' treatment a psychiatrist's opinion was sought. Some of the more chronic cases of Type 2 were recommended phenobarbitone 1, 2 gr. (32 mg.) t.d.s. for periods of two to four weeks.

Reassurance was considered of prime importance in the immediate treatment; this consisted either, in persuading the man who admitted that he was afraid that his was by no means a unique case—indeed, common to a greater or lesser degree was feeling like him—or in persuading the man who complained of severe headaches or pain over the heart that he was not suffering from a brain tumour or an incurable heart disease. Where possible, arrangements were made with the unit for the patient to be transferred to its detachments outside the Antwerp area.

Observations

A few general remarks might here be made about the effects of the bombardment on the mass of the troops stationed in my area. Many units for months on end were working at high pressure in most vulnerable surroundings, as in petrol or port installations. Few units were fortunate enough to escape having some casualties, and most of us had our full quota of near misses. It was natural enough, therefore, that we all became heartily sick of these things, and many admitted to me, after it was all over, that they felt they could not have stood up to it much longer. The night-time was a much greater strain than the day, and I occupied on duty, and men were generally liable to smoke and drink more than usual.

I have yet to meet the man who was totally unaffected by these bombs—I doubt if he even exists. Many felt tired owing to repeated sleepless nights. To begin with we were able to sleep during the attack—unless one fell too close; but after a time we found ourselves constantly listening for the drone of the engines, following their flight down to earth—and the waiting for the next one.

The lack of this anticipation is one of the things to be said for the rockets, which arrived without preliminary warning, for even a door banging or the sound of a factory siren was liable, after a time, to worry us.

Summary

A series of 63 cases of "exhaustion" seen over a four-months period of the bombardment of Antwerp are reviewed. They are classified into two main types according to their presenting symptoms. No more specialized classification has been attempted.

Treatment consisted of reassurance, rest, and sedatives, in unit lines where possible. Of the cases 30.1% were severe enough to warrant admission to hospital.

The report ends with a few general remarks about the reaction of the mass of the troops to the attack.

REPORT ON MENTAL NURSING

Recommendations designed to give mental nursing a status equal to that of any branch of nursing are contained in a report issued by the Minister of Health and the Minister of Education. The report is that of the Subcommittee on Mental Nursing and the Nursing of the Mentally Defective appointed by the Athlone Interdepartmental Committee on Nursing Services. Mr. Bevan recently described the report in Parliament as a most valuable survey, and said he proposed to obtain without delay the views of the various interested bodies regarding the recommendations, many of which would require legislation.

General Recommendations

The subcommittee considers that the mental nursing service should be held to be comparable in status to any branch of the nursing

Report of Subcommittee on
Mental Nursing H.M. Stationery

profession. "That it is not so is to a large extent due to the public attitude towards mental illness, which involves ignorance of the high qualities of mind and body demanded from the mental nursing service. There are some 29,000 nurses employed in this service—16,400 women and 12,600 men—and we think that, if recruitment is to be stimulated and the quality of the recruits improved, all possible steps must be taken to give the mental nurse a status comparable to that occupied by the nurse engaged in general sick nursing." Among the main recommendations are:

State Registration—Qualified mental nurses should be registered by a statutory body; registration on a supplementary part of the State Register is not satisfactory. All nurses on the Register should be entitled to the designation "State-Registered Nurse." There should be one recognized qualification for the mental nurse in lieu of alternative examinations of the Royal Medical and Dental Association or through the General Nursing Council. The right to practice should rest with the General Nursing Council, subject to certain conditions, which include protection for those not holding N.M.P.A. certificates. If these conditions cannot be agreed, the subcommittee recommends legislation to establish a separate statutory body similar to the Central Midwives Board.

Recruitment and Training—Engagement of female nurses should be the responsibility of the matron, and recruits should have a medical and x-ray examination before entering a hospital. A preliminary training of at least one month is recommended before entrance to hospital. Higher posts in mental hospitals should be held only by nurses with the double qualification of mental and general nursing.

Conditions of Service, etc.—Scale of salary for the mental nurse should be higher than that for the general nursing nurse. On hours of work the introduction of a 95-hour fortnight generally is an essential step. Legislation is needed to ensure that our best qualified institutions for the mentally defective should be superintended on the same basis as nurses in mental hospitals. Under the Superannuation Act female staff should be permitted to retire at 50. There should be interchangeability of pension rights from general hospital nursing to mental hospital nursing, and vice versa. Student nurses, particularly girls, should normally live in the hospital. Periods of leave out of the hospital authorities are satisfied if the nurse is in the area of the hospital. All trained mental nurses should be permitted to live out. Ward maids should be employed where possible. The ratio of nurses on day duty to patients (1 nurse to 10 patients) should be substantially reduced.

Status of Mental Nursing

The subcommittee has no doubt that there still exists an inferior view of the nursing of the mentally ill, which is, sometimes, considered an occupation inferior to the nursing of the bodily sick. This impression contributes as much as any other factor to the difficulty when mental hospitals experience in obtaining enough female staff. It is a matter of national importance that the modern outlook on mental illness should be understood and that the value and interest of mental nursing should be recognized. While no other form of nursing makes greater demands upon the nurse, there is another side: asylums for detention and protection of the inmates have given place to mental hospitals, fully equipped with a view to the recovery of the patients.

Great advances have been made in recent years, and modern methods of physical treatment require specialized training. The medical staff now need highly skilled mental nurses to assist in carrying out the detailed technique of such methods of treatment as insulin therapy, convulsive therapy, insulin treatment, and prolonged narcosis. In all these the preparation of the patient and the equipment, the care of the patient during treatment, and the subsequent nursing demand much skill and knowledge.

On thorough investigation most cases of mental illness are found to be the result of a combination of physical and psychological factors. It follows, therefore, that the mental nurse has also to receive an adequate training in the nursing treatment of bodily ailments and diseases, both surgical and mental. There is every justification for the recognition of mental nursing as a highly skilled branch of the profession and entitled to a worthy status. The traditional stigma attached to mental illness has not yet been eradicated from the public mind, but there are signs that a more enlightened view is developing, and much could be done by judicious publicity on behalf of the mental nursing service to dispel the public feeling that contact with the mentally ill is something to be avoided.

Discipline, Food, and Recreation

The discipline of the hospital should not extend to the nurse when off duty. She should then, so far as is possible, have the personal liberty of a private individual. A small standing committee or nurses' council should be set up in each institution to scrutinize the rules, consider grievances, and suggest reforms. The cafeteria system of feeding should be introduced where possible. There should be provision for obtaining light meals and for the entertainment of

guests of both sexes in every nurses' home. Facilities for outdoor games should be available for nursing staff, and social activities and the formation of social clubs should be fostered. "Any attempt to segregate the staff is in these days an anomaly, and, if persisted in, can only lead to discontent and friction." Hospitals in rural areas might be able to organize transport to the nearest town for the use of nurses during off-duty time.

THE TEACHING OF TUBERCULOSIS

The following Memorandum on the Teaching of Tuberculosis to Medical Students has been issued by the Tuberculosis Educational Institute, Tavistock House North, Tavistock Square, London, W.C., over the signatures of Dr. Frederick Heaf (chairman) and Dr. Harley Williams (secretary):

No one will deny that the teaching of tuberculosis to medical students is far from satisfactory. It is still only too common an experience to find that a newly qualified practitioner's only acquaintance with tuberculosis is based on physical signs of cases in advanced stages of the disease and a very theoretical knowledge of sanatorium routine. The vast field of the preventive and socio-medical side of the subject and even the importance of early diagnosis are largely unknown to him, so that he enters practice quite unable to appreciate the significance of one of the commonest and most serious diseases.

In the Goodenough Report on Medical Schools it is stated that the present facilities for teaching tuberculosis vary considerably in teaching centres, and it gives two examples which indicate the differences which exist in the nature of the instruction, showing how it depends mainly on the presence or absence of a tuberculosis department or dispensary attached to the hospital of the medical school. The situation as it was in 1939 is summarized at the end of the report. At that date, of the 25 medical schools in England, Scotland, and Wales, 12 provided teaching in tuberculosis, but not in the main hospitals. Of these 12, nine made use of the treatment beds of the local authority. Four teaching hospitals made use of the facilities at special chest hospitals. Only two hospital medical schools had beds of their own reserved specially for tuberculosis cases. It would appear that in over 50% of the medical schools it was only by good fortune and not by any arrangement on the part of the authorities that the student was able to acquire knowledge on tuberculosis. In such schemes where it was possible for the student to take a course in tuberculosis it was usually quite optional and dependent on the personal inclination of the student himself. It not infrequently happened, therefore, that the student passed through his medical training seeing only a few cases of pulmonary tuberculosis, and if he did it would be those with advanced disease, so that the mental picture he formed of the disease would be one of crepitations, rales, and pulmonary cavities, and a hazy idea that all such patients require sanatorium routine with the addition of artificial pneumothorax treatment if it could be given. It is not surprising, therefore, that he does not recognize the disease until it has reached this advanced stage.

A more recent survey made by the Tuberculosis Educational Institute has revealed some improvement in the situation, particularly in the Northern medical schools. In nine teaching schools compulsory courses in tuberculosis are arranged and short periods of residence at the local authority's sanatorium are included in the curriculum. A number of visits are paid to the local dispensary so that the student begins to appreciate the socio-medical side of the problem and the value of early diagnosis. These arrangements all show how necessary it is for educational purposes to link up the tuberculosis

ices of the local authority with the medical schools. In this er local authorities might use the old advertisement slogan, : u want the goods—we have them."

ie committee of the Tuberculosis Educational Institute has given siderable attention to the undergraduate and postgraduate facilities for studying tuberculosis in all parts of the country, and it feels hat the time has come to emphasize the need for putting tuberculosis tuition in a more prominent position in the medical training of the student and to arrange, uniformly in all schools, easy access to the local authorities' tuberculosis services so that the vast amount of material being dealt with at the many dispensaries and sanatoria in the country may be used for the teaching of tuberculosis in all its aspects.

The committee strongly supports the recommendation in the Goodenough report that there should be a tuberculosis dispensary at or adjoining every parent teaching hospital and that in-patient facilities for cases of both pulmonary and non-pulmonary tuberculosis should exist in one or more of the hospitals constituting the teaching centre, provided there is a chest physician or orthopaedic surgeon in charge of the beds, or a chest hospital within easy reach. It does not, however, consider that such facilities should exclude from the curriculum a series of visits to sanatoria, for it is almost impossible to convey the meaning of sanatorium treatment to a class of students around the bedside in the wards of a general hospital.

The committee wishes to amplify the scheme of the Goodenough report by suggesting that:

1. The physician in charge of the dispensary and/or the medical superintendent of the sanatorium might with advantage be appointed a lecturer on the staff of the medical school which may be situated within the region or area which the dispensary or sanatorium serves.

2. All medical students must be attached to approved tuberculosis dispensaries as clinical clerks for short periods, during which time they should also become acquainted with the technique and organization of mass radiography.

3. Facilities should be made available for short periods of residence at approved sanatoria for medical students who wish to make a further study of the subject.

It will probably be argued that the medical curriculum is already heavy loaded and it would be difficult to find time for these suggestions. The committee is well aware of this difficulty, but would suggest that those diseases which have the highest incidence should receive priority in a teaching syllabus, even if it meant sacrificing time on the rare conditions which always have a fascination and often assume an exaggerated importance in medical education for a qualifying degree.

MEDICAL NEW YEAR HONOURS

The names of the following members of the medical profession were included in a New Year Honours List published in the *London Gazette* on Jan. 1:

G.B.E. (Military Division)

Lieut.-Gen. Sir ALEXANDER HOOD, K.C.B., C.B.E., M.D., F.R.C.P., late R.A.M.C. Honorary Physician to the King. Director-General, Army Medical Services.

K.C.I.E.

Major-Gen. HEERAJEE JEHANGIR MANOCKJEE CURSETJEE, C.S.I., D.S.O., B.Ch., I.M.S. (I.A.M.C.). Honorary Surgeon to the King. Lately Deputy Director of Medical Services, North-Western Army.
Major-Gen. (local Lieut.-Gen.) JAMES BENNETT HANCE, C.I.E., O.B.E., M.D., Director-General, Indian Medical Service.

K.C.V.O.

Brig. Sir STEWART DUKE-ELDER, M.D., D.Sc., F.R.C.S., Surgeon-Oculist to the King. Consultant Ophthalmologist to the Army.

K.B.E. (Military Division)

Major-Gen. (Temp.) FRED THOMPSON BOWERBANK, O.B.E., M.C., M.D., F.R.C.P.Ed., F.R.A.C.P., N.Z.M.C. Honorary Physician to the King. Director-General, Medical Services of N.Z. Army and Air Forces.

Acting Air Vice-Marshal STANFORD CADE, C.B., F.R.C.S., R.A.F.V.R. Consultant in Surgery, R.A.F.

Temp. Surg. Rear-Admiral GORDON GORDON-TAYLOR, C.B., O.B.E., M.S., F.R.C.S., Consultant Surgeon, R.N.

Major-Gen. (Temp.) WILLIAM HEANAGE OGILVIE, M.D., M.Ch., F.R.C.S., late R.A.M.C. Consultant Surgeon, Expeditionary Force.

Major-Gen. C. MAX PAGE, C.B., D.S.O., M.S., F.R.C.S., late R.A.M.C. Consultant Surgeon, R.A.M.C.

Temp. Surg. Rear-Admiral RICHARD ALUN ROWLANDS, C.B.E., M.D., F.R.C.P., Consultant Physician, R.N.

Major-Gen. (Temp.) ARNOLD WALMSLEY STOTT, F.R.C.P., late R.A.M.C. Physician to H.M. Household.

Acting Air Vice-Marshal CHARLES PUTNAM SYMONDS, C.B., M.D., F.R.C.P., R.A.F.V.R. Consultant in Neurology, R.A.F.

Knighthood

Major-Gen. RALPH BIGNELL AINSWORTH, C.B., D.S.O., O.B.E., M.R.C.S., Honorary Physician to the King. Director of Medical Services, Joint War Organization of the British Red Cross Society and Order of St. John.

HAROLD ARTHUR THOMAS FAIRBANK, D.S.O., O.B.E., M.S., F.R.C.S. Consultant Adviser in Orthopaedic Surgery, Ministry of Health Emergency Medical Service.

PAUL GORDON FILDES, O.B.E., M.B., F.R.S. Director of Department of Chemical Bacteriology, Medical Research Council.

ARCHIBALD MONTAGUE HENRY GRAY, C.B.E., M.D., F.R.C.P., F.R.C.S. Dermatologist, University College Hospital. Consultant Dermatologist, R.A.F. For special war services.

LIV HAN HOE, C.B.E., M.B., Ch.B.Ed. For public services in the Straits Settlements.

Lieut.-Col. NILKANTH SHRIRAM JATAR, C.I.E., D.S.O., M.R.C.S., I.M.S.(ret.). Inspector-General of Prisons, Central Provinces and Berar.

Lieut-Col SAHIB SINGH SOKHEY, M.D., I.M.S. Director, Haffkine Institute, Bombay
HENRY WADE, C.M.G., D.S.O., M.D., F.R.C.S. Ed Senior Visiting Surgeon, Bangour Emergency Hospital, West Lothian

C B (Military Division)

Surg Rear-Admiral ALBERT EDWARD MALONE, M.B., B.Ch., D.P.H., R.N.
Major-Gen DAVID CARMICHAEL MONRO C.B.E. M.B., F.R.C.S. Ed, late R.A.M.C. Honorary Surgeon to the King Professor of Military Surgery at Royal Army Medical College
Air Vice-Marshal ALAN FILMER ROOK, O.B.E., F.R.C.P. Honorary Physician to the King Consultant in Medicine, R.A.F.
Major Gen TREFRY OWEN THOMPSON, C.B.E., M.D., late R.A.M.C. Honorary Physician to the King

C B (Civil Division)

Col LAWRENCE WHITAKER HARRISON, D.S.O., F.R.C.P. Ed Adviser in Venereal Diseases, Ministry of Health
SOLLY ZUCKERMAN, D.Sc., F.R.S., M.R.C.S. Scientific Director, Royal Air Force Bombing Analysis Unit In recognition of distinguished service

C M G

ROBERT BARR MACGREGOR, M.B., M.R.C.P. Ed, Colonial Medical Service Director of Medical and Sanitary Services, Malaya

C I E

Col SOHAN LAL BHATIA, M.C. M.D., F.R.C.P., I.M.S. Inspector-General of Civil Hospitals, Assam, and lately Deputy Director-General, Indian Medical Service

C V O

IVAN WHITESIDE MAGILL, D.Sc., M.B., D.A. Senior Anaesthetist, Westminster Hospital

C B E (Military Division)

Brig (Local) JAMES DAVIDSON STUART CAMERON, M.D., F.R.C.P. Ed, R.A.M.C.
Air Vice-Marshal FRANK CUNINGHAM COWTIN, C.B., M.R.C.S., R.A.F. Honorary Surgeon to the King
Brig (Acting) JOHN MANDEVILLE MACFIE, O.B.E., M.C. M.B., Ch.B., R.A.M.C.
Surg Rear-Admiral CHARLES FOX OCTAVIUS SANKEY, O.B.E., M.B., B.S., R.N.
Surg Rear-Admiral FRANCIS JOHN DESPARD TWIGG, M.B., B.Ch., D.O.M.S., R.N.
Temp Surg Rear-Admiral ROBERT JOSEPH WILLAN, M.V.O., O.B.E., M.S., F.R.C.S., R.N. Consultant Surgeon to R.N. in Scotland Emeritus Professor of Surgery in the University of Durham

C B E (Civil Division)

GEORGE VANCE ALLEN, M.D., Colonial Medical Service Principal, College of Medicine, Singapore For services during internment
Lieut-Col RUSTAMJI BAMANJI BILLIMORIA, M.D. Honorary Medical Specialist, Indian Military Hospital, Bombay
JOHN CRUICKSHANK, M.D., Professor of Bacteriology in the University of Aberdeen For services to civil defence
DESMOND WILLIAM GEORGE FARIS, M.B. B.S., Colonial Medical Service Health Officer, Malaya For services during internment
JOHN BOWMAN HUNTER, M.C. M.Ch., F.R.C.S. Section Hospital Officer, London Emergency Medical Service
DAVID HYND, O.B.E., M.B., Ch.B., Raleigh Fitkin Mission Hospital, Bremersdorp Territorial Director of the Swaziland Branch of the British Red Cross
CHARLES FREDERIC WILLIAM ILLINGWORTH, M.D., Ch.M., F.R.C.S. Ed, F.R.F.P.S. Regius Professor of Surgery in the University of Glasgow Honorary Director of Surgical Services for the E.M.S. in Western Scotland
THOMAS POMFRET KILNER, F.R.C.S. Nuffield Professor of Plastic Surgery in the University of Oxford For services to the Ministry of Pensions
Major-Gen ROBERT WALTER DICKSON, LESLIE, C.B., O.B.E., L.R.C.P. and S.I. Regional Hospital Officer, Region 3, Emergency Medical Service
THOMAS PORTER McMURRAY, M.Ch. Belf. F.R.C.S. Ed Professor of Orthopaedic Surgery in the University of Liverpool Regional Consultant in Orthopaedic Surgery E.M.S.
JOSEPH FRANCIS ENGLEDEU PRIDEAUX, O.B.E., M.R.C.S. Deputy Director General of Medical Services Ministry of Pensions
ARTHUR CHRISTOPHER TIBBITS, M.R.C.S. D.P.H. County Medical Officer of Health, Nottinghamshire County Council For services to civil defence

O B E (Military Division)

Lieut-Col (Temp) SHIV PARSHAD BHATIA, M.B., B.S., I.A.M.C.
Group Capt FREDERICK RUSSELL CHISHOLM, M.D., F.R.C.P., R.N.Z.A.F.
Acting Wing Cmdr EDWIN DONOVAN, M.B., Ch.B., R.A.F.O.

Surg Cmdr DAVID DUNCAN, M.D., D.P.H., R.N.
Surg Lieut-Cmdr FRANK POLLARD ELLIS, M.B., Ch.B., R.N.
Col PAUL CHARLES GABOURY, M.D., R.C.A.M.C.
Squad Ldr AGNES CHRISTIAN GILLAN, M.B., Ch.B. Employed with Royal Air Force Medical Branch
Acting Wing Cmdr GEORGE BYNG GRAYLING, M.R.C.S., L.R.C.P., R.A.F.V.R.
Acting Wing Cmdr GEORGE ROY GUNN, M.B., Ch.B., R.A.F.V.R. Col (Acting) ERNEST HAMILTON HALL, M.B., B.Ch., R.A.M.C.
Lieut-Col (Temp) GEORGE RONALD HARGREAVES, M.R.C.S. Specialist in Psychological Medicine, R.A.M.C.
Lieut-Col (Temp) WILLIAM HERBERT HARGREAVES, M.R.C.P., R.A.M.C.
Group Capt JAMES MACCONNELL KILPATRICK, M.B., B.Ch., D.P.H., R.A.F.
Acting Squadron Leader HENRY TRESTON MACAULAY, R.A.F.V.R.
Col JOHN COMMING MACKENZIE, R.C.A.M.C.
Surg Cmdr JOHN WENDELL MACLEOD, R.C.N.V.R.
Lieut-Col HARRY EDWARD LE MASURIER, R.C.A.M.C.
Lieut Col JULES MERCIER, R.C.A.M.C.
Temp Col HENRY ALFORD MOFFATT, D.S.O., F.R.C.S., S.A.M.C.
Surg Cmdr HARRY STAFFORD MORTON, R.C.N.V.R. (ret.)
Lieut-Col WILFRED MERLE MUSGROVE, R.C.A.M.C.
Acting Wing Cmdr KENNETH BODELL REDMOND, M.B., B.S., R.A.F.O.
Temp Acting Surg Lieut Cmdr ATTRACTA GENEVIEVE REWCASTLE, M.B., Ch.B., R.N.V.R.
Brig (Local) BERNARD EDWARD SCHLESINGER, M.D., F.R.C.P., A.M.S.
Lieut Col (Temp) PAT ADAM STEWART, M.B., Ch.B., R.A.M.C.
Col (Temp) ALFRED SWINDALE, T.D., M.D., R.A.M.C.
Col (Temp) ANDREW COPELAND TAYLOR, F.R.C.S. Ed, I.A.M.C. Professor of Clinical Surgery, Prince of Wales Medical College, Patna
Col PIERRE TREMBLAY, M.D., R.C.A.M.C.

 Fl. Lieut. CLARENCE REGINALD SLUMING, M.B., Ch.B., D.R.C.O.G., R.A.F.V.R.
 Acting Wing. Cmdr. DAVID STEVENSON, M.D., R.A.F.V.R.
 Acting Squad. Ldr. TERENCE GEORGE WARD, L.R.C.P.&S.Ed., L.D.S., R.A.F.V.R.

M.B.E. (Civil Division)

Capt. NUSSERWANJI PIROZSHAH BILLIMORIA, M.B., B.S., Honorary Ophthalmic Surgeon, Indian Military General Hospital, Bombay.
 JOHN AUSTEN PERCIVAL CAMERON, M.B., Ch.B., F.R.C.S., Colonial Medical Service. Medical Officer, Malaya. For services during internment.
 NATHANIEL CRICLOW, M.B., Ch.B., Colonial Medical Service. Medical Officer, British Solomon Islands Protectorate.
 HUBERT CRAYDEN EDMUNDS, M.R.C.S., medical missionary, Hirapur, Santal Parganas District, Bihar.
 Mrs. JEANIE GARDNER FOUGERE, M.B., Ch.B. For services to women's war organizations, Dominion of New Zealand.
 PARESH CHANDRA GUHA, L.M.S., D.T.M. Civil Surgeon (retired), Assam.
 Capt. ABDUR RAHMAN PESH IMAN, I.M.S. (I.A.M.C.), lately Sub-divisional Health Officer, Feni, Bengal.
 NOEL JAMES LINNINGTON MARGETSON, M.D., F.R.C.S.Ed. Medical Officer, District No. 1, and Medical Officer of Health, Montserrat, Leeward Islands.
 ANANT KRISHNAJI NULKAR, L.M.S., Civil Medical Practitioner, Indian Military Hospital, Poona.
 DOUGLAS ALKINS SKAN, M.R.C.S., Colonial Medical Service. Pathologist, Nyasaland.
 HUGH SMITH, M.B., Ch.B. For services during internment in Malaya.
 Rai Bahadur RAM SWARUP SRIVASTAVA, M.B., Civil Surgeon (retired), Dehra Dun, United Provinces.
 RAM LAL TULI, M.B., B.S., D.P.H., D.T.M. Deputy Director of Public Health (Temporary), Central Provinces and Berar.
 Major CHARLES MARK ERNEST WARNER, M.R.C.S. Port Health Officer, Calcutta.
 WILLIAM DE VEEVER WISHART, M.B., C.M. Municipal Health Officer, British Guiana.

Hon. M.B.E. (Civil Division)

MUNIR KHALIL MISHALANY, M.D. Assistant Senior Medical Officer, Palestine.

Kaisar-i-Hind Gold Medal

JAMES WILLIAM BOTTOMS, M.B., B.S., medical missionary, Baptist Mission Hospital, Chandraghona, Chittagong Hill Tracts, Bengal.
 MADELINE ROSA SHEARBURN, M.B., B.S., doctor-in-charge, Zenana Mission Hospital, Tank, N.W.F.P.

In the New Year Honours List, published on Jan. 1, Prof. A. V. Hill, Sc.D., F.R.S., one of the secretaries of the Royal Society, was appointed a Member of the Order of the Companions of Honour. Major-Gen. A. B. Austin, late the Army Dental Corps, Honorary Dental Surgeon to the King, was appointed C.B.; and James Gray, Sc.D., LL.D., F.R.S., professor of zoology in the University of Cambridge, and Prof. H. D. Kay, D.Sc., F.R.S., director of the National Institute for Research in Dairying, University of Reading, both received the C.B.E.

The King, on the recommendation of the Secretary of State for Scotland, has approved the appointment of John Jardine, O.B.E., I.D., F.R.C.S.Ed., to be chairman of the General Board of Control for Scotland in succession to Sir John Jeffrey, K.C.B., who retired on Dec. 31. Dr. Jardine has been a commissioner in the Board since October, 1939, holding the post of principal assistant secretary in the Scottish Education Department. Sir John Jeffrey has had a long association with public health and poor-law administration in Scotland, becoming Secretary to the Department of Health for Scotland in 1929 and Permanent Under-Secretary of State for Scotland in 1933. On the reconstitution of the General Board of Control in 1939 he agreed to undertake for a period the office of chairman.

Reports of Societies

ABDOMINAL INCISIONS

At a meeting of the Section of Surgery of the Royal Society of Medicine on Jan. 2, with Mr. E. F. FINCH in the chair, a discussion on abdominal incisions was opened by Major-Gen. W. H. OGILVIE, who was warmly congratulated by the president, speaking on behalf of the Section, on the announcement made on the previous day that the King had conferred on him the honour of knighthood.

Major-Gen. Ogilvie said that the making of abdominal incisions was a subject which it was well to bring into open debate from time to time, although he knew too much about himself and his fellow-surgeons to expect that discussion would change their views to any great extent. Most surgeons regarded their own particular form of incision in the same way as they regarded their motor-car or fountain-pen—when they had one that suited them they stuck to it although there might be better ones on the market. Their discussion should be confined to methods of approach to organs which lay inside the peritoneal cavity and incisions through the abdominal wall in the ordinary sense. The purpose of an abdominal incision was to give access to the part to be attacked and room for the required job to be done. It should be reasonably extensible and should interfere as little as possible with the function of the abdominal wall and leave it as strong as it was before. While extensibility was demanded, they were not asking for an incision which would cover any wildly wrong diagnosis, but only one which would allow a reasonable latitude in scope. The first essential of an incision was that it should be rightly placed; the second, that it should be large enough to admit the surgeon's hands and the ordinary tools of his craft. Fagge uttered a true aphorism when he said, "Always make your incision twice as long as you think it ought to be, and then you will not have to enlarge it much."

Before opening the abdomen at all the surgeon must ask himself what he was proposing to do and what else he might possibly be forced to do. He must have some idea of what organ he proposed to attack or at least in which compartment of the abdomen he was going to perform. He could extend the standard incision to a length of 12 in. (30 cm.) or more without gross structural damage, but it was seldom right that he should do so. The difficulty arose most acutely in operations for abdominal emergencies. An incision correctly planned for acute appendicitis could be extended to cope with an appendix which was gangrenous, but could not be enlarged with impunity to deal with a duodenal perforation, an inflamed gall-bladder, a gangrenous pancreas, or a ruptured ectopic gestation. While the standard incisions could be—though they seldom should be—extended, there were inextensible incisions, such as those much above the umbilicus, cramped by the narrow epigastric angle. Another criterion of a good incision was that it should do the least possible harm to the abdominal wall itself, the structures under it, and the patient. In making an incision the possibility of adhesions to the deeper surface of the abdominal wall must be taken into account. Fixation of the already fixed did not matter, it was only fixation of the mobile which caused symptoms; thus adhesions to the colon or liver were relatively harmless, but those involving the small intestine might be harmful or even dangerous.

Foremost among the incisions to which unqualified support could be given were the lateral incisions, which were steadily increasing in popularity. They gave excellent access to any structure lying on the same side between the pylorus and the pubis. Within the last two years they had in his practice largely ousted the lower paramedian and median incisions for nearly all purposes. He was tending to abandon all incisions which involved the separation of planes and the retraction of layers. Concerning closure, repair was the function of the tissues, and stitches did no more than bring them into apposition and hold them there. There was no key layer in the abdominal cavity; all must be taken into account and all must heal equally well. In lateral incisions three layers of suture were required; in median and paramedian, one layer only was closed above the peritoneum, and here, therefore, the unsupported suture was not enough; it should be interrupted, or, if continuous, it should

by mattress sutures of unsorbable material. As for poor incisions, he mentioned with disapproval "trans-rectus" incisions, and in particular Battle's incision.

Adequate Access and Firm Scarring

Mr. DIGBY CHAMBERLAIN said that three things had to be borne in mind when making an abdominal incision: adequate access to the structure to be operated on, the leaving of a firm scar after healing; and (a minor consideration) a cosmetic result. Concerning incisional hernia and burst abdomen, he referred to a paper by E. S. J. King, of Melbourne, in the *British Journal of Surgery* (1935, 23, 35), in which he expressed the opinion that such hernias started by the cutting out of the peritoneal stitches or the escape of a tag of omentum between them. As for the size of the incision, it had been said that if one was in a strange country and required an abdominal operation one should ask which surgeon made the biggest incision and go to him. Inadequate incisions might mean that diseases in the abdomen which were unsuspected were missed. Every abdominal exploration should allow the surgeon to pass in review quickly the important organs inside the abdomen. The firmness of the scar depended largely on the suturing of the peritoneum. Adequate suturing of that layer would prevent the incidence of post-operative hernia or burst abdomen, and such suturing was as much dependent on the anaesthetist as on the surgeon. In making an abdominal incision nerves should be avoided, and muscles were better displaced than divided. As a standard incision he used the paramedian in operations for the stomach and duodenum. Paramedian incisions were perfectly adequate for colon work. For operations on the biliary tract he used a right paramedian incision almost exclusively. In closing the abdomen he used a continuous catgut stitch for the peritoneum and if it was thin he took a small piece of the under-surface of the rectus muscle with each stitch in order to reinforce it. He added that abdominal incisions on the whole were not a matter of great interest to surgeons, who only too often left it to their assistants to close the abdomen, but, however much he listened to the assistant, he considered that the surgeon should close at least the peritoneum in view of the importance of that step in relation to incisional hernia.

Prof. JOHN BEATTIE made some general observations on the metabolic disturbances which followed the infliction of a surgical wound and on the physiology of healing. He stressed in particular the need for a high protein intake, and also pointed out the function of cortin in promoting repair in cases of injury, and the high vitamin C requirements in view of the increased production of cortin.

The PRESIDENT referred to the firmly rooted idea among students that an incision began to heal at one end and the process of healing continued gradually towards the other end, so that they had a prejudice against a long incision, which they thought took a longer time to heal. He also asked for an opinion about stab-drawing of the abdomen.

Mr. RODNEY MADGOT said that he had been brought up on vertical incisions, he was taught median and paramedian incisions, and gradually, lately, he had been going more oblique. The transverse incision had the disadvantages that it took a long time to make, was very bloody, and left a weak abdominal wall, so that hernia was prone to arise afterwards.

For and Against Battle's

Sir CLAUDE FRANKAU said that thirty years ago he was a convinced "muscle-splitter," but very soon he abandoned the practice. Contrary to General Ogilvie, in certain conditions he supported Battle's incision. It was the only adequate and proper incision for an appendix about which one was sure. It gave perfectly good access, no nerve was injured and no vital spot was obtained if care was taken to drain at the upper end. Lord Moyrhan once spoke of the mercifulness of the long incision. Arising out of that was the great desirability that the incision should be such that heavy retraction was not wanted afterwards. The worst thing for the patient in any abdominal operation was for the surgeon to be required to use any form of heavy retraction; it should be as light as possible.

Mr. W. E. TANNER said that when he was a house-surgeon he watched Arbuthnot Lane perform his operations. When

operating for a bad peritonitis he did not close the peritoneum at all. He put a tube right along the wound and closed up the other layers. His idea was that paralytic ileus or dilatation of the stomach in these cases was caused by distension in the abdomen. He was bound to say that he saw some of these cases heal perfectly.

Mr. HAROLD DODD said that a very good incision for the appendix, which would deal also with the ruptured ectopic, and which was coming into greater use, was the Ruthersford Morrison iliac incision, often described by Prof. Grey Turner. The gridiron incision was attractive but difficult. He had given up midline incisions on account of the likelihood of hernia. He emphasized the importance of careful protection of the wound edges if first-class healing and freedom from burst abdomen or incisional hernia were desired.

In some further discussion Battle's incision was condemned and defended. One speaker said that as a house-surgeon he had two surgeons above him, one of whom practised Battle's and the other the gridiron, and as a consequence of the results he saw he would never use the former. The gridiron found more advocates than critics. Mr. SOLLY COHEN said he had never seen an obstruction after a gridiron incision, and he believed that Surg. Rear-Adm. Gordon-Taylor once stated that he had never had to open an abdomen for obstruction following that incision. A registrar, Mr. MUNRO, urged the value of a short incision in certain cases, and expressed himself rather surprised at the tendency to long incisions by his seniors.

General OGILVIE, in reply, said that it was undoubtedly the right thing not to use the main incision for drainage, but to make a separate stab. He protested against some of the eccentric incisions—"alphabetical incisions" they had been called in the course of the discussion because a number of letters of the alphabet appeared to be imitated—which were published in certain literature, particularly American. They belonged, he said, rather to the tradition of Heath Robinson than to that of John Hunter. With good anaesthesia especially with field block of the abdominal wall, he thought that everything desired could be got out of the median incision, and he had had no misfortunes with it. It was true that one was dealing with only one layer, but with a tremendously strong layer which could be sutured with the utmost security. He thought that the controversy over Battle's incision should be left where it was.

Mr. CHAMBERLAIN, also in reply, said that one speaker had mentioned Lane's practice of suturing the abdomen and leaving the peritoneum unsutured. He could not subscribe to that procedure and he hoped that no one in that company was now in favour of it.

Correspondence

R.M.B.F. Christmas Gifts

SIR.—It is with great pleasure that I can now announce that the Christmas Gifts appeal which I launched through your columns has reached the magnificent total of £2,127—a new record. In view of the high prices and the scarcity of the amenities of life I asked my colleagues for £2,000, a sum which, in view of last year's record, I scarcely dared to hope would be achieved, but which has actually been passed by a handsome margin. This means that all our beneficiaries are receiving £4 as a Christmas gift, and there is enough over to give some of the poorest £2 for the New Year.

My committee and I are deeply conscious of the great help afforded by the medical press in supporting and giving publicity to this appeal, and to you and your colleagues of the press as well as to all the generous contributors in the profession we tender our most cordial and grateful thanks.—I am, etc.,

ARNOLD LAWSON,

President, Royal Medical Benevolent Fund

Printer, S.W.15.

A Fundamental Principle

SIR.—On reading Prof. J. A. Ryle's letter (Dec. 29, 1945, p. 936) I was amazed and distressed to find one of the leaders of our profession advocating "some measure of direction" of

doctors. Conversation with many doctors in this industrial region has convinced me that we are against any direction, to a man. Most of us joined the profession with the idea of working freely where we liked, and in whatever branch we liked. We did not then think of national socialism, totalitarian methods, direction, and control. If our freedom is going to be taken away, some of us are seriously and regretfully considering the question of giving up what has been our life's work, and finding some other occupation in more congenial circumstances and surroundings.

It is strange that having passed through the war with the slogan of "freedom" in the forefront, individual effort, enterprise, and freedom are now regarded as evil things by the powers that be. It will be a bad day for the patients when doctors are directed where they shall work, what work they shall do, and how they shall do it.

Prof. Ryle speaks from the security and altitude of a professorial chair at Oxford. Is he himself willing to be directed as to "the form, place, and type of work" he is to do? Is he willing, if "the under-privileged and under-doctoring sections of the community" require his services, to be directed to work as a panel doctor, or a physician, in Rotherham or, say, Barnsley? Is not the truth of the matter that Prof. Ryle pictures himself under a State medical service directing others, but not being directed himself?—I am, etc.,

Rotherham.

ERIC COLDREY.

SIR,—Prof. Ryle regards the present distribution of medical man-power as unfair. Presumably he means unfair to the general public and not to the medical profession. But all sorts of things are unfair to the general public—for example, the distribution of diamonds, Rolls Royce motor-cars, fur coats, caviare, smoked salmon, and country estates. All the world knows that the problem of socializing the medical services is one of the simplest, because the capital value of the profession is relatively small; whereas to nationalize the patent-medicine industries would upset all kinds of vested interests.

The scarcity of medical men in the pre-war distressed areas was caused by the local population being unable to remunerate the profession sufficiently well to attract doctors and by the local authorities being unwilling to provide efficient medical services out of local funds. Doctors who might have been tempted to work voluntarily in these areas preferred to join the medical missionary societies.

It seems to me that if such facilities as health centres and modern hospitals are first provided in these areas, and if doctors are offered reasonable salaries, sufficient medical personnel will migrate voluntarily to these parts of the country, for there they are sure to find excellent clinical material. Whereas Prof. Ryle wants direction of medical personnel, I ask for efficiency and modern facilities, and maintain that the power of direction not only is unnecessary but is an indication of incompetent administration.—I am, etc.,

London, W.1.

WILFRED SHAW.

SIR,—Your footnote to Prof. J. A. Ryle's letter underlines also the statement of the Negotiating Committee that the problem of maldistribution exists. This must have annual results of ill-health, incapacity, and mortality in the big manufacturing areas of Britain which are of great importance for the immediate future if our economic position is to be stabilized. These sanitary areas are as much a part of our national inheritance as the tradition of liberty. Our profession has a duty not only to each individual patient and doctor but to the nation as a whole, and this duty is, out of present resources to give a disinterested medical service at the earliest possible moment. If we have the complete and efficient medical care of the industrial populations as the responsibility of the next generation of doctors, which is what the Negotiating Committee and your footnote suggest, millions of employees and their families will have, for the next seven years or so, medical attention which is admitted to be unsatisfactory.

This is a perpetuation of the pre-war mentality which handed on responsibility for rearmament from Government to Government, and if we believe medical treatment is any use at all I do not see how we can tolerate it. We could not reject the heritage of Governmental inefficiency when war came in 1939,

and we cannot safely reject it in peace. If we object to Governmental direction we must direct ourselves. The Negotiating Committee should aim at immediate terms of service which should make it very well worth while for the best men to move to the Black Country or elsewhere, and should appeal for volunteers in an intensive campaign, so that this generation faces the problem. There seem four reasons why medical men do not move where they are most needed, three justifiable—children, health, finance. The commonest, least important, and most powerful—disinclination—it is the collective responsibility of the profession to overcome, and we, like the Government, will be judged by our collective efficiency. If we fail we cannot blame the Government for attempting direction.—I am, etc.,

Hove.

WILLIAM BOURNE.

Increasing the Number of Doctors

SIR,—In your note appended to Prof. J. A. Ryle's letter (Dec. 29, p. 936) on the question of direction of medical men you say that the proper solution of the problem of distribution of doctors is an increase in their number. I am sure that Prof. Ryle would agree that such an increase is urgently needed if the public is to get the service it needs, though it may not follow that this will abolish the uneven distribution of medical manpower without the Government retaining some such power of direction as is suggested in Dr. A. G. Winter's proposal (p. 936).

So far, however, there has been little evidence to indicate that the Government is particularly concerned with increasing the number of practising medical men and women. I understand that the proposal of the Goodenough Committee that all the London medical schools should accept a quota of women students is now being implemented. The effect of this will be to reduce the numbers of men accepted by such schools until such time as the accommodation for students can be materially increased. The immediate effect of the adoption of such a policy must be to decrease the number of practising doctors, as there is a well-known wastage of women through marriage and other domestic causes. It is a fair estimate to assume that some 30% of the women admitted under the new proposals will not be practising five to ten years after qualification, and the present shortage will be accentuated until the schools have enlarged their capacity. The only proposal for such enlargement which seems likely to materialize in the immediate future is the removal of Charing Cross and St. George's Hospitals to suburban sites. These two schools at present admit some 70 students annually, and this number should be increased to about 200 when their new hospitals have been built and equipped. This means that accommodation for an additional 130 students will ultimately become available, and a recent announcement in the Press suggests that the new St. George's Hospital may be ready in five years' time—possibly a rather optimistic estimate. In the meantime nine schools which at present do not admit women are to take a quota of women students. I do not know what numbers of women are to be accepted by these schools, but the average will not be more than fifteen if the number of men admitted is to be maintained at its present level. Should the average number of women admitted to these nine schools be over fifteen there is still likely to be a gross reduction of male students, and hence, allowing for the inevitable wastage of the qualified women, a total reduction in the number of practising doctors emerging from the London schools.

I have left out of account the 70 women students at present being trained at this school. If the further proposal of the Goodenough Committee that this school should be abolished is also carried into effect the prospects for increasing the number of doctors will recede even further into the distance.—I am, etc.,

West London Hospital Medical School,
Hammersmith, W.6.

MAURICE SHAW.

Principle III

SIR,—I was glad to see that Sir Ernest Graham-Little (Dec. 29, 1945, p. 936) had drawn attention to the probability that the citizen will be unable to pay both a compulsory levy and a private fee, and so the independent doctor will disappear. I had, however, assumed that the Negotiating Committee, by stating Principle III, intended to see to it that private practice

was efficiently safeguarded. This necessity has been emphasized over and over again at our Representative Meetings. Nevertheless, it may be that many of our profession are not aware of the Belfast resolution (an amended version of one by Perth), which was carried by a large majority at the last Annual Representative Meeting. I therefore ask you to allow me to repeat this resolution:

"That in any National Health Service (1) all persons compulsorily insured should have the right to opt out from the Government service in matters of medical advice and treatment and receive a financial grant towards a private contract, and that no agreement be entered into which do not effectively safeguard this right. (2) Insured patients should be in a position to assign to the hospital or nursing home of their choice any financial grant received through their health insurance authority."

Unless such a state of affairs is secured to me our fight for freedom will have been in vain. I am, etc.

Dorking.

CYRIL E. BEARE.

The Colonial Medical Service

SIR,—Your restrained leading article (Nov. 17, p. 663) will be welcomed by many members of that "nebulous organization"—the Colonial Medical Service. I feel that you might have added that many of the defects of the service should not be laid at the door of its members, but are the direct result of the Colonial system of administration plus lack of funds.

You do not mention salary and pension conditions. The newly qualified man is attracted by the rather mendacious advertisement offering him £600 p.a. or more private practice, and opportunity for specialization. When, after a few years, he realizes that he will be over 40 before attaining £1,000 p.a., that most stations offer no private practice, and that he will not be granted study leave to qualify for one of the few specialist posts, it is usually too late. If he is single or has been very lucky with private practice he can get out, with a small gratuity if he has done ten years. Otherwise he remains.

I will not comment upon your suggestions for a central directorate. Specialist appointments are being promised, but who will take them at a flat rate of £1,300 p.a.? Remember that specialists rarely qualify for high administrative posts. More frequent transfers from one Colony to another are certainly desirable. At present such a transfer is too often "an Irishman's rise." More desirable still is a reduced frequency of transfer from one station to another, which often happens several times in one tour (I do not refer to officers on specific travelling jobs). The abolition of private practice is long overdue. It creates endless jealousy and intrigue. But one is promised £150 p.a. staff pay when disallowed private practice. Will the Colonies give us £600 p.a. (or more) plus this £150? Many would be glad of the offer.

On joining the service salary should not be at a fixed rate for everyone. It should be graded according to length of qualification and possession of special qualification. Promotion should then be on merit, not largely on seniority alone. Your suggestions for short-service commissions as in the Forces, and for house appointments, are good. Technical officers labour under some unnecessary burdens designed for other needs. For example, even a highly experienced medical man is put on probation, without increments, for three years. The raw administrative cadet, who must, of course, be on probation while learning his job, is given relatively large increments in his early years. Soon after reaching 40 his salary is equal to that of the M.O. Again, the language examination should not be compulsory in all posts—e.g., for laboratory workers or where the local language is unspeakable or a maze of dialects.

Pensions are quite inadequate. On the new, 1936, conditions one must serve at least 25 years and reach a fairly high administrative post to acquire the annual pension formerly attained by a plain M.O. after 20 years: this with a steadily rising cost of living both at home and in the Tropics.

Many good men are now leaving the Colonial Service, and recent, mostly wartime, recruits are far from happy. Something will have to be done. Can the Colonial system rise to it? For obvious reasons I sign myself

"WEST COAST."

Post-haemorrhagic Blindness

SIR,—Dr. James Black's interesting description of an example of blindness following haematemesis encourages me to offer some observations upon this happily rare complication, which naturally concerns the general physician however inadequate his ophthalmological approach.

My own experience is limited to two examples which, with that impish propensity of coincidences to enliven our matter-of-fact routine, occurred in the same week. My oculist colleague was, of course, quite familiar with this association of which I was then completely ignorant, but I did not find the references to the literature particularly instructive. I learnt, however, that Pergens had traced 50 cases, in 85% of which the blindness was permanent, and that males predominated, incidentally both mine were in middle-aged females. It is clear that haemorrhage *qua* haemorrhage is not the responsible factor—one excludes the temporary loss of sight that is consequent upon retinal anaemia—otherwise examples would certainly be forthcoming from military surgeons. The majority—possibly all—result from haemorrhage from the stomach or uterus, a circumstance which has led to a number of explanations, some of which have been examined by Dr. Black. The latent period is in itself puzzling: Dr. Black mentions from 12 hours to 18 days and longer after the initial haemorrhage; in my examples the interval was 16 days and 22 days respectively. Another circumstance which would appear to exclude a general cause is the occasional unilateral limitation. If toxæmia is responsible, what sort of toxin with such specificity could be indicted? Anoxæmia has been invoked to bring the condition into line with quinine amaurosis. I recollect an article on this aspect some years ago, but regret I have no note that permits an exact reference. I recollect also another article—again I cannot particularize further—in which an explanation was advanced in regard to the viscera.

This trivial contribution adds little to the elucidation of the problem, but I hope it may stimulate opinions from others more experienced.—I am, etc.

London W.

ADOLPHE ABRAM'S.

Galvanic Stimulation of Denervated Muscle

SIR,—In order to avoid undue protraction of this correspondence we are selecting the four points from Dr. R. G. Abercrombie's last letter (Dec. 22, 1945, p. 598) which cannot be allowed to pass unchallenged.

(1) The use of Tinel's sign as an index of nerve regeneration.—If a prize were to be offered for the unreliability of any particular sign of regeneration, then Tinel's would win by a big margin. It may be absent when, from other evidence, regeneration is known to be progressing satisfactorily; it may even regress for no apparent reason. Functional recovery may fail in the presence of a strongly positive and persistent Tinel. Arguments based solely on its behaviour are worthless.

(2) Facial palsy.—How does Dr. Abercrombie assess recovery quantitatively? It is difficult enough in limb muscles; it must be nearly impossible in the facial. Has he considered the possibility in his cases of recovery not being due until about the time when he first observed the "apparent acceleration"? The coincidence of improvement with the cessation of galvanic treatment may have been attributable simply to the functional maturation of the regenerating axons occurring during the period when the patient happened to be receiving no treatment.

(3) Evil effects of galvanism resulting from ionization.—Radiant energy and electrotherapy can burn a patient; valuable drugs can poison him. Our paper was addressed only to those who know how to use galvanism; and surely three minutes' treatment daily to individual muscles can scarcely be termed "long-continued" or "exceptionally intensive." Nervousness about ionization may be allayed by the use of the excellent buffer solution recommended by Holbourn and Guttmann: the stock solution contains 25 g. of Na_2HPO_4 and 12 g. of NaH_2PO_4 in one litre of tap water, diluted as required with 5 to 10 times its volume of tap water.

(4) Contractures.—Dr. Abercrombie is unfortunately correct in believing that most clinicians hold the view that under ordinary circumstances denervated muscle does not undergo

contracture. This erroneous belief is responsible for the not inconsiderable and sometimes permanent disability that has occurred in hundreds of cases of nerve injury during the last six years. Admittedly contracture of denervated muscle is not invariable, and it can be greatly aggravated by injudicious splinting; but it will occur in the unsplinted hand if movement of the paralysed part is neglected. In the many cases that we have seen the contractures developed before and not after the institution of galvanism. Furthermore, they have been seen in cases which have had no such treatment at any time. In the untreated muscle fibrosis is rapid, in the treated muscle it is not; and fibrous tissue contracts.—We are, etc.,

Nylon for Buried Sutures

SIR,—I was pleased to read in Mr. T. Russell Stevens's letter (Dec. 22, p. 901) that his experience with nylon for buried sutures supports my claims for it. I have continued to employ it for the great majority of my cases in the past twelve months, using catgut only occasionally for the purpose of comparison, except in bladder and stomach operations where it is usually employed. As a result of these comparisons I remain convinced that catgut results in greater inflammation, induration, and pain, and in a higher incidence of wound sepsis and breakdown. This is not attributed to any fault in the manufacture of the catgut but to its property, as an animal material, of provoking the inflammatory reaction necessary for its absorption.

In the last twelve months I have seen, and heard of, an unusually large number of burst abdominal wounds in cases in which catgut was used. The surgeons in all cases were men of much experience and technical skill. In those disruptions which I saw the catgut (20-day) had been almost completely digested even as early as four or five days after operation. Most of the wounds showed no macroscopical evidence of infection. It seems from this that in an assessment of the war-time catgut the rate of absorption in the body is a factor even more important than variations in size and strength—a point insufficiently stressed in the recent correspondence on this subject.

In the matter of knot-tying I feel I must point out to Mr. Stevens that there is no question of changing hands in tying the knot which I described in my article (Jan. 6, 1945, p. 12). The short end is held in one hand, usually the left, throughout, and all half-knots are tied with that hand. The question of which way the knots slide is determined purely by the relative tensions on the two ends when the half-knots are being tightened. With equal tension a flat knot is obtained, while unequal tension will always result in a sliding knot. If the same end is held taut throughout, as Mr. Stevens suggests, all the half-knots slide on the taut end, and the result is a knot which will slip relatively easily, especially with a smooth material such as nylon, even with four or five half-knots. If the tension is changed so that the third half-knot slides down the short end it acts as a lock, and the knot is secure except when thicknesses of nylon greater than 5 N are used, when the addition of a fourth half-knot is advisable. An alternative is the reef-knot with the addition of a third flat half-knot. This holds well, but the tension of the ligature or suture cannot be adjusted with the same delicacy as with the running-and-lock knot.—I am, etc.,

HERBERT A. HAXTON.

Surgical Catgut

IR.—Mr. John Hosford's letter (Nov. 10, 1945, p. 668) stated conditions experienced by myself and my surgical colleagues. There is another aspect of present-day surgical catgut to which I wish to draw attention, and that is its untrustworthiness in use. Like most surgeons I occasionally had a ruptured wound pre-war; it was usually associated with a distended abdomen and a bad chest; it happened possibly once or twice a year. War-time Michel clips and synthetic silkworm increased these cases and clean wounds began to come apart. In these cases I blamed myself for technical carelessness until six months ago when two abdominal hysterectomies, uncomplicated by either infection or chest complications, opened out completely (with the exception

of two tension sutures), one 48 hours and the other 72 hours after operation. While performing secondary suture the extraordinary feature was the complete absence of catgut; the wound had been sutured in layers with No. 1 (a stout variety) 20-day chromicized catgut. The makers investigated my complaint and proved to their own satisfaction, although not to mine, that this extraordinary rate of disappearance was due to a technical error on the part of the theatre sister. Subsequently we carried out their directions meticulously, but in addition I used deep-tension sutures of thick silk for all my abdominal wounds and continuous nylon for the skin. During the intervening six months our troubles have been definite but small, but during the last month they have been catastrophic.

Two days after a colleague had sutured a perforated duodenal ulcer the patient started vomiting and the wound was bulging, the condition became a frank intestinal obstruction, and when the wound was opened up later the same day the whole of the deeper layers had given way. Two weeks afterwards a perforation of my own had what I thought was acute dilatation of the stomach but responded to an indwelling Ryle's tube and intravenous saline. The sutures were removed on the tenth day. That night the patient coughed and felt the wound give; two coils of dilated small gut extruded; they had obviously been adherent to the wound and the cause of his early vomiting. In another case I transplanted a solitary ureter into the colon for tuberculous cystitis, leaving a small drain in the lower angle of the abdominal wound: this was removed after 48 hours, and the following day gut could be seen through the opening. At exploration the whole of the deeper layers of the wound had given way and no catgut whatsoever was visible. This case had had a previous laparotomy a few weeks earlier and the wound had healed by first intention and no adhesions were present.

A second-stage right hemicolectomy had a troublesome convalescence; when the stitches were removed on the 10th day the skin edges gaped, and on the 14th day I performed a secondary suture, when I discovered, to my amazement, that what I had taken to be a muscle basis was densely adherent small gut so affected that I had to do an excision and end-to-end anastomosis. A week ago I excised the protruding portion of rectum for a considerable prolapse in a child. I left my sutures long beyond the last knot, three strands of No. 1 20-day chromicized catgut; all three strands had come away next morning. A few days ago I saw a man upon whom I had performed a choledochotomy; he was over 16 st. (102 kg.), and made an uneventful convalescence without cough or wound suppuration. Owing to his size and the persistent biliary drainage he remained in bed about five weeks. Now, eight weeks from operation, he has an enormous ventral hernia which threatens to burst the skin.

Over many years I have made an invariable practice of using 20-day chromicized catgut, and it is an extraordinary feature that any firm should market a product which even occasionally disintegrates in a wound in 24 hours.—I am, etc.,

Halifax General Hospital.

H. I. DEITCH, M.S., F.R.C.S.

SIR,—I have no wish to enter into any acrimonious correspondence on the subject of catgut. One of the main difficulties of any surgeon is to find out the true facts of the situation, and if this discussion brings them to light I feel that I shall have done a service.

Sir Weldon Dalrymple-Champneys (Dec. 29, p. 937) says he is in a position to contradict several statements that I made, yet curiously enough his statements are at variance with certain statements made in a brochure issued by the Ligature Department of the London Hospital, which states that "the intestines used for sterile surgical catgut at the London Hospital are from New Zealand milk lambs"; yet he states that it is untrue when I say that the material for making catgut is imported. I was also informed by a representative of a catgut firm that they were not allowed to use mercuric salts in surgical catgut. This again is entirely at variance with the brochure referred to above. When one finds such contradictory statements what is one to believe?

I would suggest that the real test would be to make available supplies of Davis and Geck's catgut, at a price comparable to the English catgut, and see which surgeons prefer. T. J. diffi-

culty in any controversy of this nature is that political and commercial interests are apt to affect the scientific atmosphere—I am, etc.,

Howe

H J MCCURRICH

The Child with Frequent Colds

SIR,—We were interested to read the letters commenting on our article. We do not feel that there is any controversy with Dr F M Mallinson (Nov 10, 1945, p 667) who stresses the importance of the infective factor in the environment. It is apparent that the majority of the cases seen by us fall into the group whose infection is derived from contact at school, but we entirely agree with Dr Mallinson on the importance of the family as a source of infection. A comprehensive examination of the affected individual should, however, precede the extension of the investigation to the family. We doubt whether detailed investigations of the children's home conditions would give us greater knowledge of the social background of these children than is already known from social surveys done on various classes of the population. Such extensive studies would have been difficult and possibly misleading under war conditions. We did not extend our investigations to a larger number of children as we did not feel that there would be significant differences in the results.

Dr Anne Greig (Nov 17, p 703) should not assume that we regarded the anaemia as being 'more or less' unimportant. The anaemia affecting a number of the children was of the microcytic type, and our mean haemoglobin levels corresponded to those obtained in large numbers of school children during 1944 in London and Edinburgh. They corresponded therefore, to those found in the general school population, and we did not think that the anaemia was evidence of some defect connected with the frequent colds. The colds were not more frequent in the anaemic children, nor was the positive Mantoux test related to the degree of anaemia. Dr Greig is justified in her suggestion that conditions in other parts of the country might have given rise to different conclusions, and it would be interesting to compare studies done in Glasgow with the one we have completed. We doubt whether the differences would be very great.

Some correspondents mentioned the importance of excess of carbohydrate in the diet, and some stressed the nervous factor and "coddling" of these children, without giving any evidence to substantiate these theories. Many parents were very worried about the frequent colds and accepted our reassurance and advice with gratitude. We do not think the parents would share the view of your correspondent who accused us of treating these children like "cases".

Our conclusions are based on the results of clinical and laboratory investigations, and we did not concern ourselves with the treatment of this condition. We should be interested to hear whether other workers on this problem have discovered constant abnormalities or defects affecting the catarrhal child. There is certainly room for much further study on this interesting and prevalent condition.—We are, etc.,

D H IRWIN
E FRANKEL

Essex County Hospital Wansford E11

SIR,—The article on colds in school children by Drs Irwin and Frankel (Oct 27, p 566) omits all reference to one common and important cause—chalk dust. The use of chalk on a blackboard and its removal with a dry duster ensures that for a considerable part of each day children who sit near the board are breathing air impregnated with highly irritating particles of dust. Even the teachers are not immune from its effects, but certain children suffer so acutely as to present a typical picture.

The usual history is that the child enjoyed very good health until going to school and still keeps well during the longer holidays. Whilst at school, however, he gets cold after cold. No sooner does he recover from one, after a period of absence from school than he returns to catch another. The clinical appearances are equally characteristic. There are, usually, some conjunctivitis and catarrhal otitis media, nasal congestion with a watery discharge, and a short dry cough without any sign of bronchitis. In short, they suggest an allergic reaction rather than an infective process. In one case I have found that during

a prolonged absence from school only one cold occurred and that followed the use of a blackboard and crayons at home.

There is no doubt that chalk dust can and does produce these effects, and I am informed that there has been an increase in allergic respiratory disorders in Derbyshire as a result of increased quarrying during the war. It is rather a prosaic explanation to offer and will not satisfy those who explain all childhood's ills by the poverty, ignorance, and stupidity of the parents, but it does account for the facts which are generally, that these children suffer from colds, not when they are at home, but only during their attendance at school.—I am, etc.,

M L POSTON

Abdominal Nerve Block

SIR,—In the *Journal* of Oct 20, 1945 (p 547) one notes with interest the technique advised by Lieut-Col F R W Kinhead Allen for blocking the ilio inguinal and ilio hypogastric nerves. However, a simpler and surer method is that described by Farr (*Practical Local Anaesthesia*). The intracutaneous wheal is raised 2 cm medial to the anterior superior spine. The needle is inserted perpendicularly backwards till it is felt to pierce the aponeurosis of the external oblique with a characteristic jerk. After the usual aspiration test, 30 ccm of 1% novocain (containing m 3 (0.18 ccm) of adrenaline) are injected without moving the needle. Both nerves are thus soaked as they lie beneath the aponeurosis and anaesthesia results within five minutes.—I am, etc.,

M ARNOLD

Spinal Analgesia in Operative Obstetrics

SIR,—The sad stories of the misadventures which have followed the use of spinal analgesia, recently published in the *Journal* would appear to support my contention that this form of analgesia should be used only when positively indicated, and then only by those who have made a special study of the technique of administration.

No one can object to an experienced anaesthetist making use of any method at which he has become specially proficient but the not uncommon practice of using spinal analgesia for straight forward uncomplicated cases simply because of its convenience can no longer be justified in view of such tragedies as have recently been reported.—I am etc.,

New Barnet Herts

JOHN ELAM

Diagnostic Acumen of the G.P.

SIR,—In the Section of Surgery of the Royal Society of Medicine on Dec 5 Mr Ernest Finch in his presidential address on the treatment of the cancer patient (reported in the *Journal* of Dec 22, 1945 p 894) spoke *inter alia* of the part played by the general practitioner in the diagnosis of early cases of cancer of the breast. He is reported as saying that "the student left his school with a definite picture of the final stages of cancer," and later that "when he [the practitioner] saw a lump in the breast with no fixity, no retraction of the nipple, and no palpable lymphatic nodes in the axilla his training led him to think and say that it was chronic mastitis or some relatively innocent condition." If Mr Finch is correct in his animadversions, one wonders, Sir, who these general practitioners might be who show such colossal ignorance of the rudiments of diagnosis, and, if they exist at all, surely their hospital training must have been defective in every way, and what of those (alleged) specialists surgical and otherwise who went through the tedious farce of teaching them? Statements like this from an eminent source call for further investigation.

For some years now the general practitioner who at one time did 90% of the midwifery in this country and did it well, has been told in season and out that he is a careless and poorly equipped accoucheur a positive danger to any woman bearing and should on no account attend a midwifery case. A specialist—a urologist I believe—implored general practitioners not to pass a catheter on any account no matter how great the patient's need for relief of acute retention but to send for the urologist, whose methods presumably were far less antiseptic than the general practitioners. And now, the unkindest cut

all, we are assured on the authority of Mr. Ernest Finch that we cannot even diagnose an early carcinoma of the breast!

No doubt the G.P. needs high flights of imaginative skill to reach such acumen in the realms of diagnosis, but he is, or must be a dull dog; and more, does anybody really believe him capable of properly writing out a panel certificate? Surely it is a waste of time and energy training a young man or woman to be an "ordinary doctor." Why not train them as specialists right away and save much time and trouble? The whole thing is preposterous, and if gentlemen like presidents of Sections must give addresses—and I suppose they must—then they should keep to their subject and avoid unfair criticism of the general practitioner, who is not the fool he is made out to be. If he is a fool at his work then it is time, and more, that the whole scheme of medical education was recast. Maybe those time-consuming hours wasted in learning the fleeting facts of physiology and the dry-as-dust bones that "present" for examination might be more profitably employed in learning to recognize the early as well as the final stages of disease.—I am, etc.,

Bournemouth.

VINCENT NORMAN.

Penicillin by Intramuscular Drip

SIR,—The note by Dr. T. A. Grimson with reference to the intramuscular drip method of administering penicillin (Dec. 15, p. 849) brings up several relevant points. Most persons with much experience of using penicillin will agree that this method is that of choice, especially when administration is to be prolonged, as it is less painful and does not disturb sleep. It is felt that so simple a technique as that described needs full publicity, as no doubt, when supplies become more easily available, its use in general practice may well become of importance.

The total dosage for the twenty-four hours should be made up to a volume of half a pint (280 c.cm.) only, as larger quantities tend to cause pain and boggy swelling around the needle site. The lateral aspect of the thigh is the site of election, and the institution of regular quadriceps exercises appears to facilitate absorption. Using the standard E.M.S. transfusion set, 8 drops a minute has been found to be the average rate of drip to allow for the half-pint to be run in during the twenty-four-hour period. A strip of plaster stuck down the side of the bottle with the appropriate times graduated upon it keeps a check on the rate of flow, and it has been found that most patients of any intelligence will help any shortage of nursing staff by watching their own drip and adjusting the screw-clip from time to time as required. A stainless-steel saline infusion needle with side perforation in addition to a terminal one, such as that of Souttar, which is $2\frac{1}{2}$ in. (6.35 cm.) long and has an S.W.G. of 14, was found to be ideal as it exactly fits the connexion on the tubing of the transfusion set, is long enough to lie snugly and flat on the thigh, and is less liable to get blocked than a needle with only the terminal opening.

The presence of sepsis at the needle site, which is referred to in the *Lancet* (Dec. 22, p. 817), is very common, and there appears no certain method of preventing its occurrence, although fortunately the pus is usually sterile and any sepsis as a rule clears up completely in two or three days. It would seem that changing the needle site from one thigh to the other frequently (every two or three days) reduces the liability to this mishap, as it also reduces the tendency to any local pain or swelling.—I am, etc.,

Hatch End, Middlesex.

MARTIN STRATFORD.

Treatment of Breast Abscess

SIR,—With reference to the very interesting letter of Dr. nie Fulton on infective mastitis (Dec. 15, p. 862) may I add a note on treatment.

Of the 27 cases which came to my notice in January and February, 1944, 24 were in multiparous married women and 3 in virgin unmarried nulliparae. Of the 24 multiparae 12 were seen in the first six weeks of the puerperium and were to be seen in the presupplicative stage of the infection. In 20 of the cases the infection was circumareolar. Three of the cases were interstitial and one retromammary. At this stage the breast on palpation presented a definite painful irregular

mass. There was some slight temperature and pulse. The course of treatment was the same in all cases.

Stilboestrol medication was started to inhibit lactation, if any. Simultaneously the affected breast (or breasts) was irradiated with deep infra-red rays. Fifteen minutes under the rays night and morning was sufficient. The surface of the treated area looked now like mild sunburn. After three days of such treatment the breast was opened with a deep incision radiating from the nipple. Gas and oxygen were used as an anaesthetic. Frank white creamy pus was always evident after the three-days irradiation. The micro-organism was predominantly staphylococcus. Infra-red irradiation was started as before, and the incision healed from below upwards with healthy granulations, leaving a pink flexible scar, thus conserving the artistic and ornamental value of this organ. Three cases were pre-operatively treated with the sulpha drugs and poultices, but it took two days longer for fluctuation and abscess formation to occur, and at least ten days to heal, even with the application of urea crystals, leaving a contracted ugly scar. With the advent of penicillin deep infra-red irradiation, by causing a local hyperaemia, would bring more leucocytes to the site of infection, and a higher concentration of penicillin or the sulpha drugs if they were used. Abscess formation and fluctuation occurred more quickly by this method than with poultices and the sulpha drugs. Healing of the incision took place more readily, as there was a greater flood of fibrocytes, phagocytes, and healthy serum brought to the part.

More use could be made of infra-red rays for local infections elsewhere, and with the added aid of penicillin and the sulpha group of drugs local infections could be quickly and safely dealt with. All the above cases gave a successful and satisfactory result with this treatment.—I am, etc.,

Ryde.

JOHN M. CAMPBELL.

Treatment of Amoebiasis

SIR,—I was very interested in a letter in your columns recently concerning amoebiasis among ex-prisoners of war from the Far East. As an ex-prisoner of war myself I can state that very many of these cases received no specific treatment whatsoever and some as little as 1 gr. (65 mg.) of emetine hydrochloride owing to the lack of drug supplies. I impressed on all my amoebic cases that they had not been cured, even though their symptoms had abated, and that they would require further investigation and treatment on return to the U.K.

It can be taken almost dogmatically that any diarrhoea, flatulence, or other mild gastro-intestinal disturbances occurring in repatriated prisoners of war from the Far East should be regarded as amoebiasis unless repeated examinations of the stools have proved negative. This is especially the case if there is any enlargement or tenderness of the liver, or if the caecum or sigmoid colon is palpable and tender.

Examinations of the stools can easily be carried out by the general practitioner, but I would like to emphasize that it is essential for success to have a fresh specimen. The stool should be passed at the consulting-rooms into a warmed bedpan. It will be remembered that to the naked eye the amoebic stool is bulky, foul-smelling, acid to litmus, and may contain blood and mucus. If a little of the mucus is now transferred on to a slide and mixed with equal parts of normal saline *E. histolytica* can be seen under low power as glistening refractile specks, and if these are examined under high power the contained R.B.C.s, movement of the pseudopodia, and the differentiated endoplasm and ectoplasm will identify the parasite. Cysts are less easy to identify and the stool should be sent to the pathologist, since in the case of cysts a fresh stool is not essential. The presence of *E. coli*, Charcot-Leyden crystals, or the spirochaete of Werner, or other similar motile organisms, should be viewed with grave suspicion. Sigmoidoscopy should be carried out in all cases before pronouncing the patient free from infection; the parasites may often be found in a smear taken directly in this way, or a typical flask-shaped ulcer with undermined edges may be seen even when no sign of disease is found on ordinary stool examinations.

Even when all findings are negative, if the symptoms persist without apparent cause a full course of specific treatment should be given. Relapse is extremely common among incompletely treated cases, and the combined treatment recommended by Manson-Bahr is in my experience most satisfactory. The patient should be kept strictly in bed; 1 gr. (65 mg.) of emetine hydrochloride subcutaneously each night should be given for 10 nights. Soda bicarb. gr. 30 (2 g.) daily by mouth enhances

the effect of the emetine. This should be accompanied or followed by emetine bismuth iodide 3 gr (0.2 g) nightly by mouth for 10 days. At the same time 8 oz (240 ccm) of selen retention enema should be given daily. This should be followed by carbarsone 4 gr (0.25 g) twice daily for a fortnight. A short time after treatment the stools should again be examined, and a sigmoid examination carried out as a test of cure. Might I plead that any investigation and treatment less than that outlined above is not doing full justice to the patient—I am, etc.

Glasgow

E SNELL

Shortage of Nurses

SIR—Dr T R Aynsley in his letter (Dec 15, p 865) on the shortage of nurses shows a lamentable ignorance of the industrial nurse's function when he writes of her "waiting for minor accidents preparatory to sending them to a hospital outpatient department." Primary treatment is but a small part of the industrial nurse's work which is mainly preventive in character and the nurse who has obtained her certificate in industrial nursing which requires among other things a sound knowledge of social science will justly resent Dr Aynsley's criticism of her work. Does he think that nurses engaged in other branches of preventive medicine, such as health visiting are also wasting their time?

Dr Aynsley need not be unduly disturbed in mind, however, as nurses are not "directed" to industry, and it is only possible to "entice" nurses who are approved for the work by the Appointments Department of the Ministry of Labour. Such approval is given to only a few classes of nurses who are not subject to direction—e.g., married women with children or whose husbands are in the Forces abroad.

The number of trained nurses employed in industry is estimated at 5,000, which works out at about one trained nurse to each 3,000 persons employed. Nurses below the age of 27 other than a few special classes, have long since been directed to other spheres of work, so that the only trained nurses in industry who could be directed to hospital work are those with special qualifications and skill who are better employed where they are—I am, etc.

The Butterley Co. Ltd. Derby

G F KEATINGE

Benjamin Rush's Death

SIR—In "Nova et Vetera" (Dec 22, 1945, p 893) it is stated that Benjamin Rush's death "is alleged to have been hastened by injudicious bleeding." It is a pity that this old libel should have been even tentatively resurrected, for there is nothing in it. Rush was, of course, a violent advocate of bleeding. His "three tens" treatment for yellow fever—10 oz (300 ccm) blood, 10 grains (650 mg) of calomel, and 10 grains of jalap—is historical, was certainly ferocious, and probably cost a good many lives. But his own death actually was due to pleurisy, and the rumour from America that reached Lettison in 1813 and started the story in England was stated by Dr Mease, one of Rush's oldest friends, to have been circulated by his enemies to gratify "the little and mean spirits amongst us who exulted in the report of his having fallen a victim to the depleting system and who will be glad to find the report has been circulated in Europe" (Pettigrew's *Lettison*, vol 3, p 22). The whole story is retold in my *Lettison* (London, 1933, p 375) and in *Benjamin Rush* by N G Goodman (Philadelphia, 1934, p 346).

It is curious that the same story should have been circulated about Lettison's son, John Miers, whose death, according to gossip recorded by Farington in his *Diary* (vol 1, p 294), was said to have been caused by over-bleeding. This was equally fallacious and probably due to the same cause—jealousy—I am, etc.

London W 1

J JOHNSTON ABRAHAM

Doctors Wanted for Boys' Clubs

SIR—It is a regrettable gap in our health and social services that, while machinery is in being for periodic examination by qualified doctors of children of school age none exists for the "vetting" of the adolescent boy or girl at work other than that provided by some enlightened industrialists.

For many years clubs affiliated to the London Federation of Boys' Clubs or its parent body, the National Association of

Boys' Clubs, have done something to make good this deficiency by arranging for local doctors or senior medical students to "vet" their boys, to the great benefit of the health of the boys and the peace of mind of their leaders.

My own boys' club in Hoxton has for nearly twenty years now been fortunate enough to have the services voluntarily given, of house physicians or last year students from a great teaching hospital in East London. Other clubs have not been so fortunate, and the purpose of this letter is to seek through your *Journal* the help of other doctors and students who may be able to spend a couple of evening hours weekly or fortnightly in a boys club in some part of London. Though in the nature of a "busman's" holiday, there is enjoyment in such work, especially as time passes and "the Doc" becomes like the managers, a part of the furniture of the club, the London boy requires no praise from me.

If any young physicians reading this feel they can give a little time to this invaluable work, I shall be grateful if they would write to me at 222, Blackfriars Road SE 1, when I shall be able to put them into touch with a club in their neighbourhood.—I am, etc.

JAN M LESLIE
Chairman London Federation of Boys' Clubs

Obituary

W B FEATHERSTONE, M.D., J.P.

Dr William Barltrop Featherstone, who died on Dec 25, had been a member of the British Medical Association for 60 years. Though professionally a general practitioner, his long association with public work in Birmingham—he was a member of the City Council for 37 years—stands as an example to others. At the funeral representatives were present from many aspects of the life of Birmingham and particularly of Erdington.

Born on May 16, 1861, at Laleham in the house where Dr Thomas Aynsley had lived before becoming headmaster of Rugby School, he was educated at Queen's College and at Mason's College, Birmingham, and won prize medals in four subjects and qualified M.R.C.S. in 1887, graduated M.B. Lond. with first-class honours in 1887, and practised for 10 years later. When newly qualified he was beaten by a more senior man in a close contest for the post of house physician at the Birmingham Medical School. Featherstone decided that he would wait for the next vacancy and felt after some time that the public health service was not sufficiently absorbing to him. He had taken the D.P.H. Therefore after holding posts elsewhere he entered general practice at Erdington in 1897. For 10 years his main preoccupation was his busy practice, but he found time to develop local medical, nursing, and social work.

Moreover, in 1899 he joined as chairman of the directors of the Birmingham Erpense which in the next 46 years prospered under his energetic leadership and balanced judgment. At the arbitration of amalgamation of Erdington with Birmingham in 1911 he was a member a year later he was returned unopposed as Councillor for No. 5 Erdington on the Birmingham City Council, continuing to be a vigorous member until last October. He was opposed at only one election and was made an alderman in 1912 while still in practice. A member of the Education Committee, he was chairman of the Elementary Education Subcommittee for 14 years and spent each Easter at the annual conference of the National Union of Teachers. He was also an active member of the Hygiene and Special Schools Subcommittee and served on other important committees and boards. He was a Birmingham magistrate and for 30 years took a keen interest in local politics. When the controversy raged over the National Health Insurance Act in 1912 he was a firm supporter of moderate opinion, and for many years served on the Birmingham Panel Committee. Dr Featherstone's other public activities and the parts he played in philanthropic work were too numerous to mention here. He practised at the Grove, by Erdington Village Green, for over 40 years, and in retirement lived at Wide Green, Sutton Coldfield.

Punctual, quick, and methodical, he fulfilled each of his many duties with an ease that astonished those who knew how busy he was. He was a clear and concise speaker, and until his hearing failed a most efficient chairman, brief in utterance, far-seeing, tactful and good tempered, with a thorough grasp of the subjects to be discussed. In all things he endeavoured to keep acquaintance with what was going on. His oft repeated inquiry was "Anything fresh?" A man of affairs, he loved to have plenty of appointments to keep.

When asked if he would have preferred to be a consulting physician he replied that he had no regrets; he was deeply interested in his community and in contact with people from so many aspects of their lives. Too old for active service in either of the great wars he worked as medical officer at the Norlands Red Cross Hospital in 1914-18. He married in 1893 Isabella, daughter of Henry J. Davies, of Brooklyn, U.S.A. She brought her vigorous personality to help him in his activities and was a well-known figure in the charitable, social, and political work of Birmingham until her death in 1929. Of their two sons, the younger was killed in France in 1918; the elder, Dr. H. W. Featherstone, O.B.E., served in the R.A.M.C. in both wars.

A. SIMPSON-SMITH, M.Ch., F.R.C.S.

Temp. Lieut.-Col. Alexander Simpson-Smith, R.A.M.C., surgeon to Great Ormond Street Hospital, was reported missing at Tobruk in June, 1942, but was known to have escaped once after all casualties had been dealt with. He is now reported killed, and buried in the war cemetery at Halfaya-Sollum, aged 42.

He was educated at Workson School, at Cambridge University, and at Guy's Hospital, qualifying in 1925. He obtained the F.R.C.S. diploma in 1929, and a year later, after taking the M.Chir. degree at Cambridge, he was awarded a Richardson research fellowship at Massachusetts General Hospital, Boston. After returning to England he became resident surgical officer and radium registrar at Guy's, where he had already been junior demonstrator of anatomy and staff anaesthetist; later he was appointed resident assistant surgeon and then surgeon to outpatients at the West London Hospital and was elected to the surgical staff of the Hospital for Sick Children, Great Ormond Street. Alex. Simpson-Smith was also consulting surgeon to the Lord Mayor Treloar Cripples Hospital at Alton and to the mental hospitals at Napsbury and Shenley. He joined the B.M.A. in 1925, had been honorary secretary of the Medical Society of London and of the Clinical Section of the Royal Society of Medicine, and a member of the Council of the Harveian Society. On the outbreak of war he left his many civilian appointments to take a commission as major in the R.A.M.C., and after the fall of France went to the Middle East and served in Cairo and Tobruk with promotion to the rank of lieut.-colonel. For his work in Tobruk he was mentioned in dispatches, and a tribute to his original and successful methods of treatment has reached us from a surgeon in Rome, Dr. Giorgio Colognato, who saw the excellent results in an Italian hospital ship which carried many British prisoners of war in 1942.

News has been received from Canada of the death in Montreal of Dr. DAVID ALEXANDER SHIRRES, who was physician to the late Marquess of Aberdeen during his term as Governor-General of the Dominion. Dr. Shirres was born in Aberdeen in 1864 and studied medicine at the University of Aberdeen and at St. Bartholomew's Hospital and graduated M.B., C.M. Aberd. in 1886. He practised for a time in London in Harley Street before going to the United States in 1893, where he became professor of diseases of the nervous system in the State University of Vermont. Later he was appointed neurologist to the Montreal General Hospital.

Dr. JOHN GRACIE, consulting physician, Western Infirmary, Glasgow, died on Nov. 17, 1945. John Gracie was born at Moidart, Lochailort, Inverness-shire, in 1877. He graduated M.B., Ch.B. at Glasgow University in 1900 and became a Fellow of the Royal Faculty of Physicians and Surgeons in 1920. After graduation he engaged in general practice in the Partick district of Glasgow with his brother, the late Dr. Farquhar Gracie. During the war of 1914-18 he served in France with the R.A.M.C., and was in charge of a hospital in Marseilles. He joined the staff of the Western Infirmary in 1907, and was visiting physician from 1927 until 1942. Owing to staff shortage he was asked to retain his post as visiting physician. This he continued to do until March, 1945, despite the burden imposed upon his failing health. Dr. Gracie was honorary lecturer in clinical medicine at Glasgow University from 1930 until 1945. He was also visiting physician to Larkfield Hospital, Greenock, and Killearn E.M.S. Hospital. His advice and judgement were sound and always helpful, and by his original and kindly personality he earned the respect and affection of his colleagues and patients. He was medical superintendent to the Anchor Line, Ltd., Glasgow, and derived

great pleasure from the personal contacts that this work afforded him. However, his greatest pleasure came from his teaching and associations with medical students. They were a source of unending interest to him, and he had the remarkable facility of forming lasting friendships with students and junior colleagues. He was keenly interested in the Highlands, and took an active part in the various Highland associations, especially those which concerned themselves with the welfare of students. A keen fisher, he always looked forward to a quiet month's fishing in his native county.

News has been received of the death on Dec. 6 of Dr. ERNEST BARON ROGERS, who in 1935 went to India as medical officer to a tea-planting firm in Assam and practised at Dooars, in Bengal. He was a medical student of Guy's Hospital and took the M.R.C.S., L.R.C.P. in 1929, becoming house-surgeon to the Warneford General Hospital at Leamington Spa. Dr. Rogers was honorary secretary of the Bengal and Dooars Division of the B.M.A. in 1939 and honorary secretary of the Assam and Northern Bengal Branch in 1941-3.

Dr. ENID KESTENBERG, formerly of the Malayan Medical Service, died at Epsom on Dec. 14. Born at Kilmarnock in 1899, Enid Aimée Robertson entered Queen Margaret College, Glasgow, and obtained the M.B., Ch.B. degrees of Glasgow University in 1921. After a period with the Church of Scotland Missionary Society at Kalimpong, India, she was appointed by the Colonial Office to various posts in Malaya at Kuala Lumpur and Kuala Kangsar. She took the D.T.M.&H. in 1928 and carried out research in Malaya on tropical diseases, more particularly typhus fever, which she herself contracted in 1936 and was invalided home. When war broke out she became interested in the M.T.C., and it was then that she met her husband, Mr. Arthur Kestenberg, who survives her with a son aged 2. Her brother, Dr. R. Cecil Robertson, of Shanghai and Hong Kong, died in Japanese hands in 1942.

Dr. EDWARD MILLIKEN GOLDIE, who died suddenly on Dec. 15, 1945, was the eldest son of the late James M. Goldie, a Northumbrian who came to London and was one of a small group of civil servants who founded the Civil Service Stores about 80 years ago. He was born in 1866, and was educated at King's College School and at Edinburgh University, where he became M.B. in 1890 and M.D. in 1896: a younger brother was also in the medical profession—Dr. J. O. Goldie, who died some years ago. After qualification Dr. E. M. Goldie held a resident post at the Mental Hospital at Bootham, York, and thereafter was for some years at the Poplar and Stepney Sick Asylum (now St. Andrew's Hospital). Before the end of the last century he had started in private practice at Woodford, Essex, from which he retired about ten years ago. For many years he was visiting medical officer to the Royal Merchant Seamen's Orphanage, Snaresbrook. He is survived by his widow, formerly assistant matron at the "Poplar and Stepney," and has one son and two daughters. His modest and unassuming disposition did not conceal from those who knew him his merits as a careful and trustworthy general practitioner of the older school. He joined the British Medical Association in 1894.

Dr. HARRY CORNER, of Jersey Farm, Sandridge, St. Albans, who died on Dec. 18, 1945, aged 81, was the second son of the late Dr. F. M. Corner, of Poplar. His elder brother was the late Dr. Frank Corner, J.P., and one of the younger brothers is Mr. Edred Corner, F.R.C.S., formerly surgeon to St. Thomas's Hospital; the late Dr. Cursham Corner was a first cousin. The family are of Yorkshire origin, from the village of Lythe, near Whitby, and are related to many Yorkshire families in that part of the North Riding. Harry Corner was educated at Epsom College and at the London Hospital, where he became house-physician. He qualified as M.R.C.S., L.R.C.P. in 1888, proceeding to M.B.Lond. in 1890 and M.D. in 1892. He took up mental hospital work, was assistant medical officer at Bethlem Hospital, and finally became medical superintendent at the Earlswood Idiot Asylum. He was also at one time lecturer on neurology and psychiatry at the North-East London Postgraduate College. In his youth Corner was a very good rugby player, both for his hospital and for Kent County. After retirement he took up the breeding of pedigree Jersey cattle and made much more than a local reputation at it. He married Miss Janet Connell, who died about ten years ago, leaving two sons and a daughter. The latter is also a keen Jersey breeder, and has her own herd. Dr. Corner joined the B.M.A. in 1891.

Dr. GEORGE VICTOR BAKEWELL, who died on Dec. 19 at Beaconsfield, was chairman of the Bucks Division of the B.M.A., which he joined in 1918, and represented his

Division at two Annual Meetings. Born in 1887, he studied medicine at Cambridge University and the London Hospital, taking the English Conjoint qualifications and the B.A., M.B., B.Ch. degrees in 1912. At the London Hospital he served as house-physician, house-surgeon, and resident accoucheur, and during the war of 1914-18 held a commission in the R.A.M.C. as specialist in operative surgery with the rank of major, and was mentioned in dispatches and awarded the O.B.E. He was a past-president of the Windsor and District Medical Society, and in recent years had been medical officer in charge of the Red Cross convalescent home at Beacornish.

The death took place on Dec. 22 at the Kent and Sussex Hospital at Tunbridge Wells, of Dr. EDWARD TAYLOR, formerly honorary physician to the Hull Royal Infirmary. He was the third son of the late Thomas Coates Taylor, L.D.S., of Gooch and was educated at Drax Grammar School and the Leeds Medical School. He graduated M.B., Ch.B. with honours at Victoria University in 1898 and in the same year passed the M.R.C.S., L.R.C.P. He obtained the M.D. degree in 1902 and the membership of the Royal College of Physicians in 1904. After acting both as house-surgeon and as house-physician at the Leeds Royal Infirmary he served as a captain in the Cape Medical Staff Corps in the South African War and was awarded the Queen's and King's medals. Shortly after his return from South Africa he was appointed an honorary physician to the Hull Royal Infirmary, to which he rendered distinguished service for many years until his retirement. He was also consulting surgeon to the Beverley and Duffield Hospitals. When the Territorial Force was formed he received a commission as captain in the 5th Batt., East Yorkshire Regiment with which he was mobilized in 1914. He was given command in 1915 of the 2/1 Northumbrian Field Ambulance, which he took out to Salonika with the rank of lieutenant-colonel. He was very active in the social life of Hull and was for two years president of the Hull Literary and Philosophical Society. He was a past-president of the East Yorkshire Branch of the B.M.A. and of the Hull Medical Society. He was a Past Master of the Kingston Lodge of Freemasons, being one of three brothers to hold this office, and a P.P.G. Deacon of North and East Yorks. He leaves a widow and one son. In his younger days Dr. Taylor was a keen athlete and was particularly interested in wrestling. He was also an excellent shot with a Service rifle. He retired from practice somewhat early in life, but will be remembered by the older members of the profession in Hull and district as an able and painstaking physician who inspired the confidence of his fellow-practitioners. He was always willing and anxious to assist his colleagues, and to the younger ones his sound advice and friendly help were unselfishly accorded.—H. L. M.

Dr. CHARLES HORNE WARNER, who died at Southwell, Notts, on Dec. 29, studied medicine at the Middlesex Hospital after graduating B.Sc.Lond. in 1908, and took the M.B., B.S. degrees in 1917 and the M.D. in 1921. He was house-physician and house-surgeon at the Middlesex and assistant M.O. at the Western and Park Fever Hospitals under the Metropolitan Asylums Board. Before taking the D.P.H. and becoming M.O.H. for the Beeston and Stapleton Urban District Council Dr. Warner had been lecturer and member of the board of examiners of the Pharmaceutical Society of Great Britain. During the war of 1914-18 he held a commission in the R.A.M.C., serving as M.O. to the 1/5 London Field Ambulance and the 1/20 Battalion London Regiment. He published a number of papers on chemical subjects and an article on "Ankylostomiasis in London" in these columns on July 26, 1919. He married Dr. Refna Horne Mallet.

We regret to report the death in London of Dr. H. A. DE MORGAN, of Douglas, Isle of Man, where he had practised for the past twenty years and was much beloved by his patients. A student of the Middlesex Hospital, where one of his relatives was a surgeon and is commemorated in the name of a ward, Harold Aylmer De Morgan qualified in 1915, and after serving with the rank of captain, R.A.M.C., in the war of 1914-18 and as house-surgeon in Torbay Hospital, he took the M.B., B.S.Lond. degrees in 1920. Soon after settling in the Isle of Man he was elected honorary physician to Noble's Hospital; he was also a medical referee under the National Health Insurance Acts, and held numerous other appointments, including that of medical assessor to the Royal Courts of Justice. In 1938-9 Dr. De Morgan was president of the Isle of Man Medical Society and the Isle of Man Branch of the B.M.A., which he had joined in 1927. Though the strain of the war years must have told upon his strength he seemed in good health until November, when he came to London for specialist advice at his old hospital, and died there on Dec. 8. At the funeral

service in St. Thomas's Church, Douglas, Archdeacon Stockwood gave an address paying tribute to Dr. De Morgan's work and character. The congregation included almost every member of the medical profession in the island and representatives of the hospital committee and nursing staff.

WILLIAM HENRY OGLE WOODS, a senior member of the medical staff of the Swansea General Hospital, who died on Dec. 29, aged 70, had been chairman of the Swansea Division of the B.M.A. in 1933. The son of an Irish father and a Welsh mother, he studied medicine at Cambridge and at St. Thomas's Hospital, taking his B.A. in the Natural Sciences Tripos and becoming M.B., B.Ch. in 1901, and then served as house-surgeon at St. Thomas's and senior resident medical officer at Queen Elizabeth's Hospital. He obtained the F.R.C.S. Ed. diploma in 1902. His work at the Swansea General Hospital began as senior resident surgical officer in 1916, and from January, 1925, as an honorary anaesthetist until his appointment as superintendent surgeon in April, 1926. He became a full surgeon in 1927 and orthopaedic surgeon a year later; he was also medical officer in charge of the venereal diseases clinic. Mr. Woods suffered much disability after the amputation of one leg twenty years ago. He was, in the words of a colleague, "a painstaking surgeon whose judgment was very sound; an extraordinary man of tremendous courage, who just carried on despite his handicap, probably doing more work than any of us. A medical mind and perhaps his own experience, helped him in his orthopaedic work, and he made at least as great demands on himself as upon his patients."

B. G. S. Antes May I be allowed to pay tribute to my old chief, Surgeon-Commander A. H. D. RICHMOND, R.N.V.R., who was S.M.O. for over 2 years at H.M.S. *St. Vincent*, Gosport. I feel the profession as a whole, and the Royal Naval Medical Branch in particular, have lost a fine figure. I served under him for 10 months during parts of 1944 and 1945, and he has certainly have had a more lovable and loyal superior officer. He was a gifted organizer and knew how to obtain the best from his juniors. He had served with the R.N.V.R. during the war at Grimsby, where he was formerly a practitioner and had occupied the post of Admiralty surgeon and agent and police surgeon as well. He was universally popular at *St. Vincent*, and no one ever consulted him professionally without feeling better for it. His personality radiated confidence. In later life he battled most heroically against a big affection which needed constant watching and treatment; it might well have daunted a man of lesser spirit, and of the ultimate issue he was well aware. His sudden death after a short sharp illness in the Royal Naval Hospital at Haslar has come as a shock and sorrow to all who knew him. He has bequeathed to them the memory of a great gentleman and inspiring chief.

The following well-known medical men have died abroad: Dr. ALEJANDRO A. RAYMOND, an eminent phthisiologist of Buenos Aires, aged 67. Dr. F. H. ALBEE, a prominent orthopaedic surgeon of New York, aged 63.

Thirty-two members of the Canadian Forces who served overseas and are now demobilized have been awarded scholarships by the British Council to enable them to study in Britain. All of post-graduate standing, they have been selected in co-operation with the Canadian Department of Veterans' Affairs, and their subjects include medicine, dentistry, physics, geology, textile technology, town-planning, librarianship, economics, law, education, music and drama, and fine arts. The scholarships are for periods ranging in the first instance from six months to a year, but some may be extended. The holders of medical scholarships and the colleges, etc., at which they are now studying are: Capt. R. W. Begg, educated at Dalhousie University and was medical officer with the 1st Canadian Parachute Batt., studying pathology at Lincoln College, Oxford; Capt. J. M. Corston, of Halifax, N.S., educated at Dalhousie and Edinburgh Universities, a medical officer, studying obstetrics and gynaecology at the Radcliffe Infirmary, Oxford; Major C. Hollenberg, of Winnipeg, educated at the University of Manitoba, a medical officer, studying surgery at the University of Liverpool; Capt. G. Homer, of Winnipeg, a medical officer whose early work was among Eskimos, studying surgery at the Royal College of Surgeons; Surg. Cmdr. A. B. McCaren, of Winnipeg, educated at the University of Manitoba, studying surgery at St. Bartholomew's Hospital; Capt. W. H. Rose, of Montreal, a medical officer, studying cardiology at the British Postgraduate Medical School, London; and Major F. R. Tucker, educated at the University of Manitoba, a medical officer, studying orthopaedic surgery at the University of Liverpool.

Medico-Legal

ANTI-VIVISECTION SOCIETIES AND INCOME TAX

For over fifty years anti-vivisection societies have been granted exemption from income tax on interest on their very large investments, as the result of a finding by Mr. Justice Chitty in 1895, although in 1929 Mr. Justice Russell (now Lord Russell of Killowen) threw doubt on that decision in his judgment in the Grove-Grady will case. In 1942 Sir Leonard Rogers drew up a memorandum on "Are Anti-vivisection Societies Good Charities?" and this, by direction of the committee of the Research Defence Society, was sent to the Treasury with the request that the grounds on which anti-vivisection societies were exempted from income tax as "charities" should be reconsidered in the light of the immense advances in curative and preventive medicine due to animal experiments during the last half-century. The Inland Revenue authorities asked for evidence in support of the statements in the memorandum, and on receipt of this from nine medical and veterinary scientists a test case was heard in December, 1943, by the Special Commissioners of Income Tax. The findings of the Commissioners were cited in an article in the *British Medical Journal* of Sept. 1, 1945 (p. 291); after an appeal in the King's Bench Division of the High Court before Mr. Justice Macnaghten at the close of July. The Commissioners found that, on balance, the object of the National Anti-vivisection Society, "so far from being for the public benefit, was gravely injurious thereto, with the result that the society could not be regarded as a charity. . . . But, upon the authorities, we regard ourselves as precluded from so holding," and they therefore felt bound to allow the society's claim. Mr. Justice Macnaghten, after hearing legal arguments for two days, reversed that decision, allowed the appeal, and revoked the order granting exemption from income tax, with costs against the society.

At the close of December this case (*Inland Revenue v. The National Anti-vivisection Society*) came before the Court of Appeal, consisting of the Master of the Rolls (Lord Greene), Lord Justice MacKinnon, and Lord Justice Tucker. The Crown contended that if experiments on animals were abolished medical science and research would be retarded, and benefit to the health of the community would be frustrated. The Court, by a majority, dismissed the appeal against Mr. Justice Macnaghten's judgment, but gave leave to appeal to the House of Lords.

The Master of the Rolls in his dissenting judgment said there was nothing to be gained by pretending that vivisection did not cause pain to animals. The objects of the society, to prevent infliction of pain on animals, were clearly good in themselves and were not prevented from being so by the fact that experiments on animals might lead to benefits for mankind. Lord Justice MacKinnon, on the other hand, held that whether the objects of a trust were beneficial to the community was a question of fact to be established by evidence. Here he was satisfied that the achievement of the society's purposes would not only not be beneficial to the community but would inflict injury on all mankind. The motives of well-meaning subscribers were not material; it was for the Court to decide whether in fact the purposes of the society were of benefit to the community. Lord Justice Tucker, in his judgment agreeing that the appeal should be dismissed, said that the practice of vivisection had been legalized under safeguards, and he could not see how a trust to abolish vivisection could be a benefit to the community.

The twenty-sixth annual report of the James Mackenzie Institute Clinical Research, St. Andrews, covers the year ending July 31, 1945. As war conditions still prevailed the activities had to be confined on the restricted lines of the past few years; but 63 new cases and 521 additional notes were added to the files; 397 films were exposed in the x-ray department, and 399 examinations were carried out in the laboratories. As in former years, the voluntary medical inspection of university students was again carried out at the Institute by Dr. R. V. C. Ash. The council is now faced with the need to plan for the future and is giving close attention to the task that lies ahead, so that the resources at its command may be used to the best advantage.

Universities and Colleges

UNIVERSITY OF LONDON

A course of five public lectures on "Pharmacological Chemistry" will be given by Mr. F. Bergel, Ph.D., in the Department of Pharmacology, University College, Gower Street, W.C., on Tuesdays, at 5.15 p.m.:—Jan. 15: Survey of the fields of pharmacotherapeutics. Jan. 22: Prosthetic compounds: vitamins, hormones, and other active substances occurring in the body. Jan. 29 and Feb. 5: Symptomatic drugs: synthetic analgesics and antispasmodics. Feb. 12: Etiotropic compounds: antimicrobials. The lectures are open without fee or ticket to students of the University and others interested in the subject.

UNIVERSITY OF BIRMINGHAM

The following candidates have been approved at the examinations indicated:

M.B., Ch.B.—*†J. K. Baird, *†D. H. Barnbrook, K. D. Roberts, R. J. Bennett, D. L. Crombie, J. C. Foster, †J. C. Haworth, Rachel M. Hickinbotham, G. Jacobs, R. F. Martin, W. I. Murdoch, T. A. W. Parkes, F. C. S. Pearson, H. M. Rodger, Dorothy M. Tidmas, P. T. Walker. *Part I (Midwifery and Diseases of Women and Paediatrics)*: E. J. Allaway, A. C. Allin, P. G. Bevan, W. I. H. Bourne, J. Butler, B. O. Clements, Pamela J. Chappell, Fay P. S. Cull, S. P. Dawson, Rosemary Dearden, W. B. L. Downing, Leah M. MacN. Dunn, Margaret J. Dutton, Jeanette G. Eveson, Barbara M. Finch, D. P. Fitzgerald, Frances A. Fouracres, D. M. Garratt, Joan E. Garside, N. L. Gleiberman, F. R. Goodwin, P. H. T. Hall, Norah K. S. Howkins, Jose V. Keats, H. M. Kent, D. E. T. Laird, Sylvia E. Leather, Rosemary T. Mitter, G. C. Richards, Jeannie E. Roulston, Patricia E. Smith, J. E. Tremlett, F. E. Webb, J. T. H. Wise, C. Wood.

*With second-class honours. †Distinction in surgery. ‡Distinction in paediatrics

The following scholarships, exhibitions, and prizes have been awarded in the Faculty of Medicine:

Queen's Scholarship (Final Year): D. H. Barnbrook. *Ingleby Scholarships*: D. H. Barnbrook, J. C. Haworth. *Arthur Foxwell Memorial Medal*: J. C. Haworth. *Sampson Gamgee Memorial Medal and Priestley Smith Prize in Ophthalmology*: J. K. Baird. *Lawrence Barnard Carlton Scholarship*: E. A. Marsland. *Alexander Youngson Prize*: Dylis A. Owen, P. Goodwin.

UNIVERSITY OF BRISTOL

Mr. R. Milnes Walker has been appointed professor of surgery in succession to Prof. A. Rendle Short, who is retiring. The announcement last week stated erroneously that this is a newly established chair. The University of Bristol, since it first received its Charter in 1909, has had a chair of surgery, which has been filled in succession by Prof. James Swain, the late C. A. Morton, the late E. W. Hey Groves, and Prof. Rendle Short.

UNIVERSITY OF DURHAM

Richard Charles Browne, B.M., B.Ch., M.R.C.P., has been appointed to the Nuffield Chair of Industrial Health at Newcastle-upon-Tyne.

At a Congregation held on Dec. 21 the following medical degrees were conferred:

M.S.—R. J. Rutherford, W. K. Yeates.
M.B., B.S.—Isabel Aitchison, Lilian Alexander, Jean E. Arkle, J. Arkles, R. J. Belas, Eileen E. Cameron, Rachel Cameron, E. S. Clarke, Barbara E. Corlett, G. R. Cottrell, J. D. K. Daves, R. J. Dias, Joyce Dixon, R. H. Etherington, V. Franks, G. D. Fullerton, G. S. Graham, Jean A. Grant, V. F. Harrison, Joyce C. Harvey, Rita Hedley, G. L. Hindson, P. J. Hogg, A. S. Hughes, Patricia M. Hutchinson, A. C. Jenkins, C. Johnson, W. Latimer, Elizabeth Lawson, S. Ley, Mary Meikle, F. R. G. Mellor, M. Menzies, Jean H. Mitchell, J. S. Noble, J. Oldfield, A. C. Parry, Jean McM. Paterson, B. E. Roebuck, W. M. Ross, C. B. S. Schofield, H. L. Simon, Jean D. Smedley, E. R. Smith, F. J. Spencer, N. B. Sprague, Kathleen M. Stevens, Mary Storrier, S. M. Spiro, C. P. Tanner, T. C. Taylor, D. S. Thomson, J. N. Walton, D. D. Webster, A. E. White, Joan Williams, M. Wood, W. Wood, K. D. Woodas, W. F. M. Hudson (In absentia).

UNIVERSITY OF WALES

The following candidates for the degrees of M.B., B.Ch. at the Welsh National School of Medicine have been approved at the examinations indicated:

SURGERY.—J. W. Bowen, Gwenllian M. Griffith, D. B. Harries, K. I. Roberts, D. L. Stone (with distinction), D. R. Thomas, W. D. C. Thomas.
PATHOLOGY AND BACTERIOLOGY.—Beryl H. Jones, B. F. Richards, T. M. Warren.
PHARMACOLOGY.—S. I. Cohen, Anne Guy, Constance A. M. Llewellyn, Mary C. Sumption.
MEDICINE.—Jane W. Anderson, D. Anthony, A. J. Barry, L. A. J. Evans, I. D. Jacobs, P. G. Jagger, D. G. Jones, Enid A. Reed.
OBSTETRICS AND GYNAECOLOGY.—A. H. Beynon, Nora C. Curran, Gareth E. Davies, Margaret E. Davies, Clare G. M. Dillon, E. D. Edwards, J. M. Huxley, M. G. Jones, N. E. H. Jones, Mary Lawrence, R. Medlicott, Goronwy Owen, Barbara M. Parker, Beryl P. Roberts, K. I. Roberts, D. M. Rowlands, Jean T. Smith, D. M. Watkins.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

The William Blair-Bell Memorial Lecture, 1946, will be delivered by Dr. Leonard Colebrook, F.R.C.O.G., on Friday, Jan. 25, at 5 p.m., at the College House, 58, Queen Anne Street, W. His subject is "Looking Backwards and Forwards: Control of Infection in Obstetrics."

New regulations have been made increasing the special and general training required of candidates for admission to membership of the Royal College of Obstetricians and Gynaecologists. The regula-

tions will apply to all who sit for the membership examination for the first time in January, 1947, except those who have served in a medical capacity in the Forces during the war, who may apply for permission to take the examination at any time under the provisions of the regulations of March, 1944. Details may be obtained from the Secretary of the College, 58, Queen Anne Street, W.1. It is also the intention of the College, when facilities are available, to increase the period of training for the membership examination from the present minimum of three years to five years. Sufficient notice of this will be given to enable intending candidates to plan their courses of training.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following letter has been received by Sir Alfred Webb-Johnson, Bt., President of the Royal College of Surgeons, from Dr. Donald Balfour, Director of the Mayo Foundation, accompanying a gift of \$5,000 to the Restoration and Development Fund:

My dear Sir Alfred,

At the meeting to-day of the Medical Graduate Committee of the Mayo Foundation it was recommended to the Board of Trustees of the Mayo Properties Association that a gift be made to the Royal College of Surgeons of England on behalf of the staff of the Mayo Clinic and the faculty of the Mayo Foundation.

We hope that this gift will be received as it is given—namely, as evidence of the desire of the staff of the Clinic, particularly the surgical staff, to aid in the plans for the reconstruction of the buildings and facilities of the Royal College of Surgeons so that in this restoration the great influence of the College in elevating surgery and the surgical specialties will be continued in the future not only in the British Empire but throughout the world.—Yours sincerely,

DONALD C. BALFOUR

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF
GLASGOW

Prof. Harry Platt, M.S., F.R.C.S., will deliver the James Watson Lecture in the hall of the Royal Faculty of Physicians and Surgeons, 242, St. Vincent Street, Glasgow, on Wednesday, Jan 23, at 4 p.m. His subject is "Localized Cystic Lesions of Bone"

The American College of Surgeons has conferred (*in absentia*) its Fellowship (F.A.C.S.) on Mr E R Garnett Passe, F.R.C.S., at the meeting of the Regents in November, 1945.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the incidence of whooping-cough and of scarlet fever continued to fall, notifications being 95 and 35 fewer, respectively. Dysentery was less prevalent, with 83 fewer cases. The only disease with a greater incidence was acute pneumonia, of which there were 197 more notifications than in the preceding week.

No further cases of dysentery were reported from the large outbreak of the preceding week in Hertfordshire, Hatfield R.D. The one fresh outbreak during the week involved 10 cases in Rutland, Oakham U.D. and R.D. A large rise occurred in Surrey, from 9 to 33. The other large returns were Lancashire 52, London 20, Essex 15, Warwickshire 12, Yorks West Riding 11, and Middlesex 10.

The decrease in whooping-cough was mainly confined to the northern section of the country. The only large fluctuation in the trend of scarlet fever was a fall of 29 in London. The main changes of any size in the returns of diphtheria were decreases of 13 in both Suffolk and Yorks West Riding. The most notable of the local increases in pneumonia was in Herefordshire, Hereford R.D., where the cases rose from 1 to 51. There were rises in the notifications of measles in Norfolk 40, and Lancashire 26.

In Scotland infectious diseases were less prevalent, notifications all showing a decrease, except those for diphtheria, which rose by 2. During the past six weeks dysentery has been at the lowest level since last July. The recent outbreak of paratyphoid fever in the East Fife coast area has been traced to a girl who sold ice-cream.

Infantile Paralysis in Malta

In the last fortnight of December 33 cases were reported in the island. Among those affected were a sailor and a member of the W.R.N.S.

Week Ending December 29

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,376, whooping-cough 724, diphtheria 514, measles 565, acute pneumonia 1,118, cerebrospinal fever 38, acute poliomyelitis 25, dysentery 265, paratyphoid 5, typhoid 9.

INFECTION DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 22.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Ireland

Figures of Births and Deaths, and of *d* *et* *c* recorded under early infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland (d) The 13 principal towns in Eire

Figures of *d* *et* *c* are given no cases; a blank space denotes disease not notifiable or not return available.

Disease	1945					1944 (Corresponding Week)				
	(a)	(b)	(c)	(d)*	(e)	(a)	(b)	(c)	(d)*	(e)
Cerebral fever Deaths	43	—	13	—	2	33	2	12	—	—

Deaths (0-1 year) Infant mortality rate (per 1,000 live births)	424	62	52	49	12	420	37	75	45	31
Deaths (excluding still- births) Annual death rate (per 1,000 persons living)	6,058	979	665	234	141	5,354	785	717	223	164
Live births Annual rate per 1,000 persons living	6,890	956	841	332	239	6,857	605	889	279	257
Stillbirths Rate per 1,000 total births (including stillborn)	227	14	31	—	—	202	20	27	—	—

* Returns for infectious diseases for Eire are included in with those for the following week.

† Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

‡ Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

The Liverpool Queen Victoria District Nursing Association announces that the launching ceremony of its mobile physiotherapy unit will be performed by the Lord Mayor of Liverpool at the Central Home, 1, Princes Road, on Tuesday, Jan. 15, at 2.30 p.m. Liverpool, which was the first city to start domiciliary nursing in 1859, is now the first city to run a mobile physiotherapy unit for domiciliary massage treatment. The unit is primarily meant to serve those patients who cannot attend out-patient departments of hospitals or afford to pay an economic fee for private treatment.

The Ministry of Labour's industrial rehabilitation centre at "Woodlee," Egham, Surrey, will be formally opened on Jan. 15 by Mr. Ernest Bevin, who was Minister of Labour when the centre was established. The ceremony will be at 2.30 p.m. and visitors will be able to make a short tour of the centre to see what is being done there.

A meeting of the Food Group of the Society of Chemical Industry will be held on Wednesday, Jan. 16, at 6.30 p.m. at the rooms of the Chemical Society, Burlington House, London, W.1, to discuss the subject of science and tea. Sir Frank Engledow will open the meeting, and papers will be read by Dr. L. H. Lampitt and Dr. A. E. Bradfield. Members may introduce friends in person.

The annual general meeting of the Research Board for the Correlation of Medical Science and Physical Education will be held at the Royal Institution, 21, Albemarle Street, W.1, on Jan. 16, at 2.30 p.m. Dr. Frank Howitt, chairman of the board, will preside, and the speakers will include the Minister of Health, Mr. Aneurin Bevan, Sir Alfred Webb-Johnson, Air Marshal Sir Harold Whittingham, Sir Reginald Watson-Jones, and Brigadier F. A. E. Crew. The board's report on medical science and physical education in industry will be presented at the meeting. This is the fourth of the series; the three earlier ones, which were presented at the meeting last year, were on medical science and physical education in relation to maternity and child welfare, education, and the Services. Tickets for the meeting on Jan. 16 may be obtained from Miss Bronwen Lloyd-Williams, 37f, Regent's Park Road, London, N.W.1.

The following radiological meetings will be held in London this month: British Institute of Radiology, 32, Welbeck Street, W., Thursday, Jan. 17, 8 p.m. Prof. H. T. Flint, "Development of Ultra Short Waves." Therapy Section of Faculty of Radiologists, at Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., Friday, Jan. 18, 2.30 p.m. Discussion on "Treatment of Birthmarks, Keloids, and Warts," to be opened by Dr. S. Bryan Adams, Dr. Inez Aphthomas, Dr. J. F. Bromley, Dr. C. J. L. Thurgar, Dr. W. Shanks, Mr. J. Jackson Richmond, Dr. A. J. Durden Smith. Radiology Section of Royal Society of Medicine, 1, Wimpole Street, W., Friday, Jan. 18, 8 p.m. Papers by Dr. J. Blair Hartley, "Tomography in the Diagnosis of Lung Carcinoma"; Dr. R. A. Kemp Harper, "Some Observations on the Radiology of the Pancreas"; Dr. A. S. Johnstone, "Experimental Study of the Vertebral Venous System."

A meeting of the Tuberculosis Association will be held at 26, Portland Place, W., on Friday, Jan. 18, at 5 p.m., when Dr. Norman Tattersall will deliver his presidential address on "The Tuberculosis Service and the Future." This will be followed by a paper on "The Pathological Changes in the Pneumoconiosis of Coal-miners" by Dr. Jethro Gough. At 8 p.m. Dr. Enid M. Rogers will read a paper on "The Incidence of Tuberculosis in the Pneumoconiosis of Coal-miners."

A course of twelve lectures on "Recent Advances in Dairy Science" will open on Jan. 22 in the lecture room of the Central Laboratories, Express Dairy Co. Ltd., 133, Euston Road, London, N.W. The course, under the auspices of the Chelsea Polytechnic, is intended both for persons engaged in the control of milk in its preparation for the consumer, and for medical officers of health, public analysts, food chemists, and others concerned with milk as a foodstuff and with public health. Prof. H. D. Kay, F.R.S., director of the National Institute for Research in Dairying, will give an inaugural address on Tuesday, Jan. 15, at 6 p.m., his subject being "The Future of Dairy Research." Fee for the course £1; individual lectures 2s 6d. Applications should be sent to the Principal, Chelsea Polytechnic, Manresa Road, S.W.3.

On Thursday, Jan. 24, at 3 p.m., Dr. Clarence Crafoord, of Stockholm, will lecture before the Society of Thoracic Surgeons of Great Britain and Ireland on "Congenital Coarctation of the Aorta and its Surgical Treatment." By permission of the President and Council of the College the lecture will be given at the Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.

At a meeting of the Medical Group of the Association for Scientific Photography, to be held in the Hastings Hall, B.M.A. House, Tavistock Square, W.C., on Thursday, Jan. 24, at 6 p.m., Dr. P. Richardson-Bell will give a talk on "Medical Photography, or Photomicroscopy Medico."

Dr. Charles Hill, Secretary of the B.M.A., and Dr. Stark Murray, vice-president of the Socialist Medical Association, will speak on "The State and Your Doctor" in the series "Questions in the Air" in the Home Service programme of the B.B.C. on Jan. 18 at 7.30 p.m.

The Ministry of Health announces that the Civil Nursing Reserve, formed in 1939 to reinforce the nursing services in the event of war, is to be continued for the present. New and improved terms of service came into force on Jan. 1. These are: (1) higher salaries for all members, (2) payment for part-time service, (3) additional leave and travel facilities for certain classes. A special emergency class of the Reserve is also being created. It is for those who, through marriage or for other reasons, cannot do regular nursing work, but who would be ready to give whole- or part-time service limited to an emergency such as a widespread or local epidemic or abnormal pressure on a hospital. Work of this kind will be paid for. Emergency members must have sufficient training to be able to serve as trained nurses, assistant nurses, or nursing auxiliaries, without further nursing instruction. Members of the St. John Ambulance Brigade or the British Red Cross Society holding certain qualifications are eligible to enrol.

Sir Alexander Macgregor, medical officer of health for Glasgow, has been appointed chairman of the Scientific Advisory Committee to the Department of Health for Scotland to fill the vacancy caused by the resignation of Sir John Boyd Orr from the chairmanship on his election to Parliament. The function of the committee is to advise the Secretary of State for Scotland on the application of the results of scientific research to public health administration and to promote medical investigation designed to assist the Secretary of State in the discharge of his responsibilities for the health services in Scotland. Sir John Orr remains a member.

By an alteration in the application of the Control of Engagement Order, 1945, which took effect on Dec. 20, 1945, women pharmacists, dispensers, and drug hands, other than those working in essential undertakings, are free from control. They may take their own steps to obtain employment, and employers are free to engage them without prior permission. The Central Pharmaceutical War Committee has therefore ceased to function as an agency of the Ministry of Labour and National Service for the placing of such persons in employment, and is no longer receiving notices of vacancies. Doctors seeking to engage women dispensers and women dispensers seeking employment with doctors may now do so without reference to that committee.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Attilius Westcott, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publisher, Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcott, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the ASSOCIATION. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medicines Westcott, London*.

ANY QUESTIONS?

Treatment of Cough in Pneumonia

Q.—What is the symptomatic treatment of cough in cases of pneumonia?

A.—Cough in pneumonia requires treatment: (1) if the cough is unproductive and interfering with the patient's comfort or rest, (2) when the cough is productive but the sputum is so viscid that the cough exhausts the patient without adequate result.

When the cough is not productive it is useless and should be damped down. The milder degrees are best dealt with by the use of a codeine linctus containing, e.g., codeine phosphate (gr. 1/16 to gr. 1/8; 4 to 8 mg.), every four hours. For the more severe type of linctus heroin (gr. 1/32 to gr. 1/8; 2 to 8 mg.) should be used sufficiently often to produce the required result. Often the unproductive cough requires treatment not so much in itself as because of the pain it causes; in these cases the pain rather than the cough should be treated.

When the cough is productive warm alkaline draughts, sod. cit. and sod. bicarb. $\bar{a}\bar{a}$ gr. 15 (1 g) in 2 oz. (56 c.cm.) of warm water, four-hourly, are most useful. With these a mixture of old matured tinct. camph. co. and oxymel of squill $\bar{a}\bar{a}$ gr. 30 (2 g.) should be given. This has been proved to have an expectorant action as well as making the cough less frequent. In some of these cases there is an element of spasm and small doses of pot. iod. and stramonium are of value.

Idiopathic Hypoglycaemia

Q—(1) Is there a syndrome in which one might call idiopathic hypoglycaemia and if so what is the blood sugar curve shown in the chart come within the pressure limits of such a condition? In this case glucose at 140 mg per 100 ml was found in the urine. (2) When insulin is used in small doses is it presumed to exert its toxic effect by increasing the amount of sugar available for combustion in proportion to the stored in the liver as glycogen? Is it possible that a degree of hypoglycaemia (with symptoms) might result from an undue preparation of the latter function over the former? (3) Could you tell me a safe dose of insulin used as above, and also the approximate safe limit? Are there any recent publications on this subject and on hypoglycaemia generally, apart from those dealing exclusively with diabetes and schizophrenia?

A.—There is such a syndrome. The symptoms are very diverse and it is impossible to do justice to them in a short answer. The initial symptoms are identical with those due to an overdose of adrenaline. Indeed they are probably due to the ready response of the adrenal medulla to a falling blood sugar. Among the symptoms are sweating, weakness, tremor, dizziness, hot or cold sensations, palpitations, precordial pain, dyspnoea, and nausea.

If the hypoglycaemia is not relieved by sugar or by the response of the liver to the increased output of adrenaline, other symptoms due to starvation of the nervous system may appear. There may be visual disturbances, incoordination of the limbs, headache, disorientation in time and space, paraesthesiae, convulsions, mental disturbances of many kinds, auditory disturbances, dysarthria, urinary incontinence, and finally coma. The second group of symptoms does not occur in the comparatively mild condition of spontaneous or "idiopathic" hypoglycaemia but is common after an overdose of insulin and may be seen also in the rare condition of tumour of the islets of Langerhans. The blood sugar curve so far as it goes, is just within the limits of normal. This does not, however, exclude spontaneous hypoglycaemia. Many of these patients show normal curves unless the test is carried out for four hours, the abnormal drop being noted between the third and the fourth hour (See *Journal* leading article of Sept. 7, 1944).

Insulin has no "tonic" effect. It does, in some but not in all patients, increase the appetite, but usually only when given in a dosage sufficiently high to produce slight hypoglycaemia. In some patients hypoglycaemia produces a remarkable increase in appetite, and it is said that normally well behaved citizens have, while hypoglycaemic, broken shop windows to get at the food. Others suffer from nausea and have to be persuaded to take sugar. It is impossible to state an average dose for the purpose of increasing appetite, or the approximate maximum, for patients vary so greatly in their reactions. It is usual to give 10 units of soluble insulin before meals, and to increase the dose gradually until success is achieved, or until hypoglycaemia without increase in appetite terminates the experiment. The literature of the subject is enormous. Some of the most useful references will be found in the leading article already mentioned.

Tuberculin positive Reactors

Q—What percentage of ordinary men and women become reactors when tested with human tuberculin? What proportion of them have the disease in an active form?

A.—The proportion of tuberculin positive reactors among apparently normal adults has been the subject of a large number of surveys (Whitney, J. S., and McCaffrey, J., *Amer. Rev. Tuberc.*, 1937, 35, 597). It has been found that about 50 to 90% are positive reactors, according to their environment, the incidence of positive reactors being higher in urban than in rural areas. Judging by recent mass radiography statistics, approximately 0.5% of the adult population have active tuberculosis.

B coli Cystitis

Q—A patient has suffered for the last three years from *B. coli* cystitis due to catheterization which became necessary during an attack of intestinal colic. Alkalis, sulphonamides, mandelic acid, autoserums etc. in different hospitals have given only temporary relief. What is the correct treatment?

A.—The urinary tract should be investigated to exclude the presence of any lesion requiring surgical treatment. If the results are negative, it is next desirable to know whether these successive attacks are due to reinfection or are merely exacerbations of an infection which has persisted throughout. This can be determined by cultivating the urine during a symptom free interval, not simply by ordinary methods but by cultivating considerable volumes (e.g.,

100 ml of 1 cc in fluid media). If the urine is then bacteria free—i.e., if the attacks are due to repeated reinfection—attention might with advantage be directed to the state of the bowel, the possibility of some disorder here is suggested by the history of intestinal colic. The infecting organism is found to be still present even during a symptomless interval, more prolonged treatment with a urinary antiseptic is indicated. The sulphonamides are both the most efficient and the most suitable for prolonged administration. After an initial course of ordinary doses (3 to 4 g daily) a dose of only 0.25 g four times a day suffices to maintain the effect, and may be taken for considerable periods, without inconvenience or any but the most remote danger of toxic effects. It is presumably known from past experience which of the sulphonamides is effective in this case, for discussion of their relative merits the questioner is referred to M.R.C. War Memorandum No. 10, 2nd edition.

Penicillin in Chronic Otitis

Q—If at treatment is advised for chronic otitis media after failure of 30% spirit drops, sulphathiazole powder and boric powder in equal parts and iodized boric powder? Has penicillin been used in this condition and what is the most successful method of application?

A.—Successful treatment of chronic otitis media often depends on factors other than the type of antiseptic used. Local treatment cannot be successful if the middle ear is reinfecting by a focus in the middle ear, the nasal sinuses or the adenoids. Further, it must be possible to introduce the antiseptic into the middle ear. For this the perforation must be sufficiently large and not obstructed by granulations and the middle ear must be emptied of purulent or mucopurulent discharge by suction or Eustachian inflation. Given these conditions, penicillin will act on sensitive organisms as effectively as in other regions. It may be used in solution or in powder form. The low temperature of solutions necessary to preserve activity may cause temporary vertigo. A note on penicillin in chronic otitis media appeared in the *Journal* of Jan. 5 (p. 13).

Icteric Index

Q—Will you please give the following information about the icteric index: (1) renal threshold level, (2) highest recorded figure, (3) usual figure in a marked catarrhal or infective jaundice, (4) average normal figure, (5) figure when clinical icterus is just visible, (6) fallacies in estimation?

A.—Bilirubin appears in the urine when the icteric index is 18 and over. The highest recorded figure is not known, but indices over 400 have been mentioned. The usual figure in a marked catarrhal or infective jaundice is 50 to 100. The average normal figure is 4 to 6 and icterus usually becomes clinically apparent at 15. Fallacies in the estimation may be due to cloudiness or haemolysis in the serum or staining of the serum by pigments other than bile. A diet rich in vegetables increases the colour intensity of the serum, owing to the presence of carotin, lutein, etc., and the serum may also be coloured by drugs such as mepacrine (atebrin). It should be appreciated that figures for renal thresholds and clinical thresholds are only approximate, as the factors influencing the appearance of bile pigment in the urine, conjunctiva, and skin are complex and variable. Finally, there is not a close correlation between the icteric index and the serum bilirubin content, and high index figures merely indicate in a general way that the serum bilirubin is raised.

Miscarriages and Congenital Syphilis

Q—Is a woman showing strong evidence of congenital syphilis prone to have miscarriages as a direct result of her early previous infection? Can a congenital syphilitic, after all evidence of active disease has subsided, later develop acquired syphilis by reinfection?

A.—If the possibility of third generation syphilis is admitted—and most people nowadays regard it as proved—there seems no reason why a congenital syphilitic woman should not suffer from miscarriages as a result of her original infection. "Prone" is hardly the word, since the condition must be rare. The answer to the second part of the question is, Yes.

Corneal Ulcer and Glaucoma

Q—If atropine is instilled in elderly people with corneal ulcers is there no danger of glaucoma? If so, are such cases to be treated without atropine? Is there any alternative?

A.—Guttae atropinae 1/2% may be used in old people who have a corneal ulcer. The danger of glaucoma is very slight, whereas in such cases not treated with atropine iritis and secondary glaucoma may follow. The certainty of improving the condition outweighs the very problematical danger of glaucoma from the atropine. If the patient has a tendency to primary glaucoma, homatropine 1% could be used initially. If no rise of tension resulted atropine increasing in strength from 1/4% should be employed. In all cases of corneal ulcer it may be necessary to distinguish between glaucoma from the

mydriatic and glaucoma due to iritis or iridocyclitis. The decision often carries a heavy responsibility, since the treatment of the two conditions is entirely different.

Sex Hormones and Infertility

Q.—What is the value of injections to increase fertility in husband and wife, each aged about 40? It is not advisable to do any of the usual tests on either. I am now using progesterone, 1 mg. weekly, and testosterone propionate 1 mg., also weekly.

A.—The causes of infertility are so many and so varied that it is doubtful whether any treatment is justified without some sort of preliminary investigation. The usual tests are certainly "advisable," but presumably they have been refused by the couple in question. In that case there is much to be said for refusing treatment. The administration of progesterone to the woman presupposes that the fault is an inadequate preparation of the endometrium, by the corpus luteum, for the embedding of the ovum—in other words, that the woman is becoming pregnant but the uterus will not harbour the blastocyst. If such is the case, and it is not very likely, then the progesterone should be given during the latter half of the cycle only and in larger doses more frequently; 1 mg. weekly can have little, if any, effect, good or bad. In favour of giving testosterone to the man, it could be argued that it might increase sex desire, but this again is unlikely. There is also some evidence that small doses can stimulate the testicular tubules, but in general it can be stated that in large doses, or in small doses continued for any length of time, testosterone depresses spermatogenesis. The most that can be said for this side of the case is that the amount of testosterone given is so small that, unless it is continued for a long time, it is probably doing no harm.

Infertility is not often due to hormone deficiency *per se*, and the treatment employed here has little, if any, scientific basis. It might be regarded as a placebo and therefore of some psychological benefit, but for such a purpose many cheaper and more suitable alternatives come to mind. Even if a pregnancy occurs it will be in spite of treatment rather than because of it. The blind and empirical treatment of infertility is unsatisfactory. The indiscriminate use of sex hormones without any evidence to show that the patient is deficient in such hormones is always to be deprecated, and particularly where infertility is concerned.

Sticking-plaster

Q.—What are the constituents of common adhesive sticking-plaster? Why is it called zinc oxide plaster, and why is zinc oxide included in it? On being removed it very often leaves particles of the adhesive material on the skin; why not use some other material—for example, the American "Scotch tape"—in which the adhesive agent always prefers its own backing to the skin?

A.—The spread of common adhesive sticking-plaster consists essentially of crêpe rubber and resins, together with various plasticizers and fillers. This is still available, if required, for special purposes, such as those in which the presence of metal is undesirable, but zinc oxide has been found to be particularly suitable as a filler, and is now usually incorporated in the plaster for this purpose, quite apart from any dermatological advantages it may provide. It has, therefore, become known as zinc oxide adhesive plaster. At the present time, of course, a proportion of synthetic rubber is being used in place of the crêpe rubber, and it seems to be even better, in some cases, than the natural product, and leaves less residue on removal. We understand that the basis of American plaster is very similar to that of the British, but the method used in applying the spread to the backing differs in the two countries, and it is recognized that by using the American process a plaster is produced which leaves less residue on removal than the plaster made by the British process.

LETTERS, NOTES, ETC.

Venereology

Dr. LOWELL WEBB (Bournemouth) writes: Dr. Robert Cook (Nov. 3, p. 634) suggests that the word "venereology" should be replaced by "astartology," but this is merely playing with names, for Roman Venus is identical with Semitic Astarte, who is equated with Egyptian Isis, upon whom have descended the attributes of Hathor, the original goddess of motherhood in its purest form, which later became debased into the type of "love" usually associated with the names of Venus and Aphrodite. In fairness to the latter it should be remembered that she was only secondarily a courtesan and primarily a lady doctor: a herbalist whose special remedy was the mandrake—the original love-apple—which she wore on her girdle as a prescription for fertility and easy parturition. If only her feminine weaknesses are to be recalled and not her medical virtues then the name of Venus is appropriate for the nomenclature of "love" disease, for the deity was bisexual—as also were the mandrakes—with a female form and a bearded male counterpart, and thus aptly becomes the symbol of both the sexes in their "venereal" misfortunes.

Suggestible Warts

Dr. N. HOWARD JONES (London, W.) writes: In your "Any Questions?" (Aug. 25, p. 271) a correspondent asking advice on the treatment of multiple warts is told that "they may be cured by suggestion or clear up spontaneously. . . ." This answer has remarkable, indeed revolutionary, implications. If warts can be cured by suggestion, may not this method of treatment be applied to other tumours? Again, does not the success of psychotherapy in the treatment of warts suggest that this tumour may perhaps be the incarnate expression of a neurosis? Developing this line of thought further, may not the quality of malignancy of a cancerous tumour be sought in the tenebrous regions of the subconscious, whence it might be exorcised by deep psychotherapy? Tempting as it is to speculate further upon this new and exciting application of psychotherapeutic endeavour, I am deterred by one small point that seems to require elucidation. How does the expert who answered this question distinguish between those warts which are "cured by suggestion" and those which "clear up spontaneously"—or, in his concluding words, "may at any moment vanish without a trace"?

Service Conditions and the Ethical Code

"HIPPOCRATES" writes: I was consulted recently by a dental officer attached to one of the armed Forces who had the misfortune to scratch his finger while attending to a patient and to develop a syphilitic sore at the site of the injury. At the voluntary hospital to which he had been referred for investigation he was treated with great consideration, care being taken to preserve as much secrecy as possible in view of his professional status, but his medical officer colleagues, to whom he had, of course, reported the matter, appeared to treat it as a joke. He was then sent to a Service hospital for treatment, and the driver of his vehicle refused to carry his case when he saw which department he was destined to enter. No attempt was made to soften the blow to a professional colleague who had contracted the disease accidentally in the execution of his duties, and he had to line up with the other patients of all ranks for his injections, which were administered by N.C.O.s, apparently without any direct supervision in the absence of a medical officer. He was therefore exposed to the risk of recognition at some future date by fellow-patients from all parts of the country. I understand that several dental officers have had similar misfortune and similar treatment, but having no desire to advertise the facts, which might damn them afterwards in their professional life, they have suffered in silence. If this is true—and I have no reason to doubt the veracity of my patient—it would appear that Service conditions tend to produce a much lower ethical code than that which is current in civilian practice, and the dental profession must have a very poor opinion of us.

LONDON SATURDAY JANUARY 19 1946

SPRUE IN INDIA

A CLINICAL SURVEY OF 600 CASES

BY

K. D. KEEL, M.D., Lieut.-Col., R.A.M.C. AND J. P. BOUND, M.B., Capt., R.A.M.C.

(From Sprue Research Team, Poona)

During the years 1942-4 British troops poured into India, finding their way into Bengal, the Arakan, to Imphal in Assam, and over the border into North Burma, the Chindit forces leading the way. In these areas dysentery and malaria were rife, as was that ill-defined syndrome of sprue. The object of this paper is to present observations, concerning aetiological factors, made on 600 cases of sprue; to describe the clinical picture; and to point out inadequacies in our present techniques of investigation. This seems all the more necessary as considerable numbers of such cases are being returned to England incompletely treated and ripe for relapse.

The difficulty here is well exemplified by the fact that no two authoritative definitions in textbooks are compatible. For the present purpose sprue is defined as a syndrome, consisting of diarrhoea, with the passage of light-coloured stools of high fat content, sore tongue, flatulent dyspepsia, and emaciation—all of these features being grossly variable in their presence or absence at one time and in their relation to one another. The term "parasprue" appears to serve no useful clinical purpose, and has not been adopted.

Malnutrition may manifest itself as the sprue syndrome. Steatorrhoea, however, is too variable a feature upon which to separate the two. The syndrome, as defined above, has been diagnosed as sprue even in the presence of an isolated normal faecal fat.

Seasonal Incidence

There are three seasons in India: the "cold," from October to February, with hot dry days and cool nights; the "hot" season, from March to June, when both day and night are almost unbearable; and the monsoon or rainy season, from June to September, when there is a slight decrease of temperature and much increase of swamp, flies, mosquitoes, and their accompanying diseases. In the hills, as at Imphal, the heat

FIG. 1.—Monthly incidence of sprue in India and North Burma.

is not so extreme and the rains are heavier and of longer duration. Throughout India the incidence of sprue was highest in May and June, and minimal in November, December, and January in both 1943 and 1944 (Fig. 1). This seasonal incidence applies whether the cases originated in the cool hills of Assam (54%) or in the hot plains of Bengal and Bihar (23%) or from the rest of India (23%).

Geographical Distribution

The geographical distribution of 450 cases was as follows: Assam and North Burma, 54.2%; Bengal and Bihar, 23.1%; South India and Ceylon, 9.1%; Bombay Presidency, 8.9%; North-West and Central India, 4.7%. In view of the vast and frequent movements of troops occurring at the time, inferences must be limited. But it would seem justifiable to say that Assam, Bengal, and Bihar presented an environment favourable to the onset of sprue. In the Bombay Presidency, too, the incidence is almost equal to the rest of Southern India and Ceylon. In the Bombay Presidency the Western Ghats produce a moist, relatively cool climate during the months of maximal incidence. That cool, rainy conditions should be favourable to the development of sprue emphasizes its relationship with hill diarrhoea and the likelihood of relapse or occurrence in temperate climates.

Within a climatic zone sprue is regional. Of the cases here reported 14% occurred near Imphal and the high incidence from this place continued long after the siege had been raised. Chittagong (9%), on the coast at the edge of the Ganges delta, produced a nest of cases—six from one aerodrome in two weeks. The difference in climate of these two places illustrates how the local regional factor may supersede that of the climate.

Duration of Service in India

The maximal incidence occurred after one or two years' service in India—45% of all cases, as shown in Table I. The earliest incidence was in the Red Sea, on the way out to India. Army statistics have shown that heat effects *per se* diminish

TABLE I.—Period of Tropical Service before Onset of Sprue (475 Cases)

6 mths or less	6 mths. to 1 yr	1-2 yrs	2-3 yrs	3-4 yrs	4-5 yrs.	Over 5 yrs
8.6%	15.8%	45.4%	24.9%	2.3%	0.9%	2.1%

very rapidly after the first hot season, so that adaptation to heat, excessive sweating, etc., are probably not important. Again, before the war tropical sprue was associated with long tropical residence.

Relation to Dysentery and Malaria

There has for long been a suspected relationship between sprue and dysentery. The following observations clarify the issue.

1. A comparison of the seasonal incidence of sprue and dysentery (amoebic and bacillary), in the same region over the same time, is shown in Fig. 2. All cases of both diseases were drawn from Assam, North Burma, and Bengal during the years 1943 and 1944. It will be seen that the incidence of sprue precedes that of dysentery surprisingly clearly, in a manner that makes it very unlikely that sprue follows an attack of dysentery at all commonly. Rather the reverse is suggested. The relation to chronic or relapsing dysentery is, of course, not to be derived from such cases.

2. The incidence of dysentery preceding sprue (23.6%) is shown in Table II. In 16.7% of cases dysentery had occurred more than

one month previously. In nearly 7% it had occurred within one month of the onset. In 340 control cases the incidence of dysentery was nearly 21%. The incidence is not significantly higher in those with sprue.

3. In individual cases a close relation is sometimes found to exist between an attack of amoebic or bacillary dysentery and the sudden passage of tropical sprue stools. It is difficult to believe that this is entirely fortuitous, though the effects of dysentery may be non-specific in activating the latent syndrome.

A group of 87 cases labelled "malnutrition" drawn from the Chindit Forces in June and July, 1944, were found to

FIG. 2.—Comparison of monthly incidence of sprue (302 cases) and bacillary and amoebic dysentery (2,200 cases) in Bengal, Assam, and North Burma, 1943 and 1944. (Dysentery curve by courtesy of Lieut.-Col. C. S. Seward, R.A.M.C.)

include 52 patients with the syndrome of sprue. These cases were seen under circumstances that rendered investigation incomplete, but glossitis, with diarrhoea, pale stools, flatulent dyspepsia, and marked emaciation, was present. Fat analysis of stools in 15 cases showed 12 with faecal fat over 30%. Malaria was found clinically and by positive blood-slide in 42%. Response to sprue therapy was unsatisfactory in many, but improved dramatically after malaria had developed and been treated. This effect of malaria and/or antimalarial therapy on the sprue syndrome was repeatedly demonstrated. If sprue is present concomitant latent malaria undoubtedly exacerbates it.

Complexion

Racial selectivity of sprue is said to be according to pigmentation. The darkest negroes do not get it at all. In dark Indians it is said not to occur, while the brunt of the incidence falls

TABLE II.—Incidence of Dysentery Preceding Sprue (525 Cases), and in Control Cases (340)

Dysentery	More than One Month before Onset of Sprue	Within One Month of Onset of Sprue	In Control Cases
Bacillary	8.0%	2.5%	6.6%
Amoebic	5.1%	3.8%	6.8%
Bacillary and amoebic ..	1.7%	0.2%	2.4%
Clinical	1.9%	0.4%	5.0%
Totals	16.7%	6.9%	—
Total dysentery ..		23.6%	20.8%
No dysentery ..		76.4%	79.2%

on Anglo-Indians and Europeans. It is undoubtedly true that Indian troops have developed the full syndrome of sprue during the war, though difficulty in diagnosis is increased by the commonness of malnutritional anaemias. In British troops, though there is no difference in the incidence between dark and fair, it is the latter who have provided the majority of severe cases.

Diet

Most troops first developed diarrhoea under jungle warfare conditions, but many were on ordinary field service rations. A large number of cases developed diarrhoea on a diet consisting of: protein, 95–103 g.; fat, 114–143 g.; carbohydrate, 425–435 g.; with calcium, 1.6–1.7 g.; iron, 20–25 mg.; vitamin A, 1,450 i.u.; thiamine, 1.2–1.8 mg.; riboflavin 2.1 mg.;

niacin, 16.3 mg.; ascorbic acid, 6 mg. (supplementary tablets, 50 mg., were added). It is interesting that this diet, well balanced and adequate on paper, was found monotonous, and parts of it distasteful, so that men were vomiting while trying to eat, and within 4 to 6 weeks on the diet developed diarrhoea and later sore tongue. Such was the story in the group of cases described above from Chindit forces.

Coincident dysentery and malaria must have played a part in the development of symptoms, but the stories of these patients strongly emphasize the psychological necessity for palatability of diet, as well as the correct caloric and vitamin value.

Clinical Picture

In these years 1943 and 1944 the clinical picture of sprue has been modified. The following is a brief description of the types seen.

The Classical Picture of Sprue.—This is well known. Its characteristics are a long history of some years' diarrhoea, with sometimes transient sore tongue. Asthenia, slight at first, increases with each bout and between them; the tongue becomes more sore, red, and smooth; loss of weight and pale large stools, at first intermittent, then become constant. Dyspepsia and distension are persistent. Emaciation progresses until the most stubborn officer is constrained to report sick some months or a year after he has suspected what was wrong with him. On examination signs are marked—a smooth sore tongue, abdominal distension, complete achlorhydria, high stool fat (40 to 50%), and macrocytic anaemia are all usually present with emaciation. This type of case was not common in our series.

Acute Sprue—Mild and Severe Forms.—In contrast to the classical picture the following is the type of story of the majority of our cases.

Onset.—A man aged about 25 arrives in India. During his first year he goes through jungle training and contracts the usual short fevers, dysentery, etc. He is sent to Assam after this and becomes involved in the fighting round Imphal and afterwards across into Burma. In these arduous circumstances he lives for varying periods, from a few weeks to months, on an adequate but monotonous diet, described previously. He naturally, therefore, attributes his onset of diarrhoea after 3 to 6 weeks to this. Diarrhoea may be acute of dysenteric type or insidious in onset; a week or two later anorexia becomes marked, and at the same time soreness of the tongue is noticed. Flatulent dyspepsia with heartburn increases, and vomiting occurs. He reports sick. Rapid improvement ensues if he is put in hospital on ordinary diet. The tongue is clear within a few days and the diarrhoea stops. His case is very much like that of clinical dysentery; exudate may or may not be found in the stools. He returns to duty feeling fairly fit. Within a week or two the diarrhoea returns; the stools are pale, sometimes quite fluid, sometimes large and bulky. He returns to hospital with the typical sprue syndrome, and finds his way in due course back to base, as either a mild or a severe case.

(a) *Acute Sprue (Mild).*—By the time the base is reached (perhaps 1 to 2 weeks are spent in transit hospitals) the man is apparently well. The tongue is normal; the stools coloured. Weight is not much reduced. He responds well to treatment and may be sent back to duty in a lower category. After a few weeks he again relapses and re-enters hospital. He repeats this tantalizing part of his story anything from two to six times before he is finally boarded out of India, still perhaps appearing well but now with glossitis or angular stomatitis and persistent distension. The stools are still pale, though their fat content may not be much raised.

(b) *Acute Sprue (Severe).*—The acute attack proceeds straight from onset to produce a dehydrated, emaciated patient with gross distension and a smooth, dry tongue. Steatorrhoea is present; anaemia may develop suddenly, necessitating transfusion; hypotension is present, and response to treatment is often satisfactory. Such cases form about one in ten of those seen. After months of treatment weight is slowly restored, two or three major or minor relapses occurring in hospital, particularly when the diet is increased. Finally he too is evacuated from India. On the average, with mild and severe cases, the period between onset and evacuation has been about one year.

Post-dysenteric Sprue.—During or after an attack of dysentery (usually amoebic) there occasionally develops a sore tongue, and stools are pale and contain 30 to 40% of fat. This change usually lasts for about a month, then clearing, but may continue and turn into a long-standing case of sprue. After repeated attacks of dysentery steatorrhoea may come on

insidiously over months with but little diarrhoea (3 to 4 stools a day) and minimal dyspepsia and glossitis

A man with glossitis angular stomatitis, marked emaciation, steatorrhoea, but no diarrhoea (2 to 3 stools a day) and no dyspepsia, with stool examination repeatedly negative for exudate and amoebae died suddenly of a perforating ulcer of the caecum. Necropsy revealed a normal stomach and small-intestine mucosa, but gross amoebic ulceration from caecum to rectum was found

This case suggests that the colon may be involved in the production of the sprue syndrome. The case also is of interest in that it was for 10 days diagnosed and treated as sprue. The patient did not respond to sprue diet and liver extract by mouth

Subacute Hepatic Necrosis and Sprue—Though subacute hepatic necrosis is not common, several instances of the condition showing the sprue syndrome have been seen at a time when jaundice was absent, bile pigment was absent from the urine and present in the faeces. The sprue symptoms, including the tongue and steatorrhoea, have improved as the liver has diminished in size

Steatorrhoea with Minimal Glossitis—This clinical picture of 'incomplete sprue' as described by Manson-Bahr (1943) has been seen in 3.6% of cases. It has most often been found in fat analysis of the stools of chronic cases of diarrhoea treated as chronic dysenteries. Chronic diarrhoea in itself does not produce a rise in faecal fat as judged from chronic amoebic dysenteries so examined. Further examination of such cases of steatorrhoea brings to light achlorhydria and other changes suggestive of sprue. Response to sprue diet is good, but sore tongue may develop on it. These cases form one extremity, so to speak, of the sprue syndrome. Time often draws them further into the group. Giardiasis and tabes mesenterica cases have not been included in this group

Glossitis with Minimal Steatorrhoea—At the other extremity of the syndrome is the condition described by Manson Bahr as 'larval sprue' glossitis with slight, if any, steatorrhoea. Differential diagnosis from pellagra is sometimes made by the later appearance of the steatorrhoea dyspepsia etc.—some times not. Hamilton Fairley (1936) in his cases found 20% with less than 25% total faecal fat. In our own series 20% of cases had total faecal fat of less than 30%. It is probable that the numbers with normal faecal fat would be greatly reduced if the examination was repeatedly performed, which it never has been. Secondly, the percentage of fat is erroneous by the standard techniques used. These considerations lessen the importance of this apparently exceptional group of cases. The clinical features of such 'low faecal fat' cases were not distinguishable from the others. Such cases are no milder, and their prognosis appears no better so far as response to treatment and tendency to relapse are concerned. The group provides many examples of the type of case which repeatedly relapsed in India before being evacuated

Characteristic Symptoms and Signs

Mouth Lesions—Glossitis has been practically constant (96%). The longer cases are observed the fewer exceptions are found. Soreness of the tip of the tongue, with redness comes first, spreading to the sides. The changes are very variable, the tongue may become smooth and depapillated in a few days, and recover equally quickly. Tongue changes coincide to a day or two with diarrhoea in many cases. Glossitis responds surprisingly quickly to diet alone, but often nicotinic acid and riboflavin have seemed to accelerate improvement. Cheilitis and angular stomatitis have not been so common (40%), nor so quick in response to treatment. Fissures of the tongue may be congenital or acquired. It seems that the congenital type may deepen and ulcerate in their depth, the acquired may appear with or without oedema of the tongue. Response to treatment has shown shallowness and disappearance of some, while others, presumably congenital, are unaffected. The typical magenta tongue of riboflavin deficiency has not been seen

Appetite—Variability from voracity to extreme anorexia is, in all phases of the disease as characteristic as either variation alone. The mechanism relating normal appetite to physiological need seems grossly deranged. While a return of appetite is welcomed, rash increase of diet subsequently produces dyspepsia, diarrhoea, and return of anorexia. This illustrates the

process of relapse in unsupervised patients after discharge from hospital

Vomiting has been present in 18%, particularly in cases of acute onset. Heartburn is common (70%) and causes considerable distress. Dysphagia has not been marked. Dyspepsia of the flatulent type is practically constant (94%). Fats exacerbate it, in spite of it, gastric acidity is usually normal—in at least 66%.

Distension—One of the salient signs of sprue, distension comes early and disappears late, if not last of all. It is maximal in the hypogastrium. Abdominal girth alters by only 1 to 2 in (2.5 to 5 cm), though the patient's sensations lead one to expect more. Barium meal examinations did not show convincing evidence of small intestine dilatation, but one instance of megacolon was found in a patient who was not more distended than the others and whose progress was better than the average. At his own wish he was retained in India under observation. When last seen 1½ years later, he was quite well on active service. Actual dilatation of, as well as reflexes from the gut producing loss of tone of abdominal muscles, provides two elements in the production of distension. The latter would appear to be a common mechanism in sprue

Diarrhoea—This constant symptom is of first importance in diagnosis and management of sprue. Diarrhoea is often as acute though not as painful as in dysentery, and 15 to 20 watery pale stools are passed daily. Even the response to sulphaguanidine is similar to that in dysentery, but the stools are pale with no exudate, and there is no pyrexia or leucocytosis. The onset of sprue is often sudden and unexpected. An example of this is provided by a soldier who set off for his day's jungle training. Unusual and plentiful borborygmi with flatulence induced him to go to stool. On rising he turned, and what he saw frightened him, for, as he put it, he thought he had passed a 'white elephant's stool'. Diarrhoea preceded sore tongue by about six weeks in 80% of cases. Glossitis precedes diarrhoea very rarely. In a few instances asthenia marked and persistent has been a presenting symptom before diarrhoea

Emaciation—On admission most patients had lost some 25% of the normal Indian body weight. One-third returned only to within 19 lb (8.6 kg) of their normal weight by the time they were evacuated. The average loss ranged from 20 to 60 lb (9 to 27 kg) at a body weight of 130 to 195 lb (59 to 88 kg) respectively

Cramps and Tetany—Cramps, usually in calves and thighs, were present in 25% of cases. No observations on calcium and phosphates could be undertaken. Plain skiagrams showed no osteoporosis. Chvostek's and Trousseau's signs have been negative except in one case which later developed gross tetany while being shown at a clinical meeting. Total blood calcium was returned as 12 mg per 100 ccm. Though mental change was marked, there was no hyperventilation. Response to liver nicotinic acid, calcium gluconate, salines, and transfusion though satisfactory clinically, was unsatisfactory as to interpretation

Skin Changes—Dry skin is a common complaint, with falling out of hair. Scaling of parakeratotic nature has occurred in 27% of cases. It improves on treatment and body cleanliness—a luxury many men have been without. Follicular hyperkeratosis also clears rapidly in hospital. These changes suggested vitamin A deficiency, but dark-adaptation tests done in 20 cases were normal with one exception only. Pigmentation, usually consisting of scattered patches, occurred in 4%. In one case it suggested haemochromatosis. The liver was enlarged, but no glycosuria existed. The distribution has not suggested pellagra, nor has any been seen in the mucous membranes

Circulatory Changes—Hypotension—blood pressure below 100/70—occurred in only 8% of cases. These were all severe, with persistent signs of dehydration and low urinary chlorides. The hypotension persists, and rises only slowly in response to treatment. It is stable, pulse pressure alters little on exercise, and Aalsmeer's test with adrenaline shows only a slight fall in diastolic level—nothing to suggest thiamin deficiency. Oedema has not been at all prominent. No evidence of left- or right-sided heart failure has been found. Screening has shown no change in heart size or shape but this examination has not been done on severe cases

Signs of Vitamin Deficiencies.—It was thought that these cases would present examples of typical deficiency states. This has not been so. **Vitamin A.**—The skin changes mentioned above were at one time taken as examples of A-deficiency, but normal dark-adaptation made this doubtful. Improvement in the skin condition occurs rapidly without any specific therapy. No evidence of deficiency of the other fat-soluble vitamins, D and K, has been found, in that no osteoporosis has been seen, and tetany was present in one case only, with normal blood calcium. The prothrombin time in several cases has been normal. **Nicotinic Acid.**—Most of the tongues seen have suggested this deficiency, but rapid response to a diet without addition of nicotinic acid therapeutically in many cases is surprising. In other more obdurate cases nicotinic acid has been effective. **Riboflavin.**—Though glossitis, with angular stomatitis, has been common, magenta tongues have not, and the rest of the syndrome—circumcorneal vascularization conjunctivitis, rosacea, etc.—has been absent. No case showing evidence of thiamin deficiency or scurvy has been seen.

Investigations

Appearance of Stools.—The typical large pale frothy stool is well known. Pallor at some period is almost constant: it is due not only to the fat in the stool but to alteration of the bile pigment. This alteration usually accompanies a raised stool fat, but not always, so that a pale stool may have a normal fat content, and a coloured stool may have a raised fat. It is important to remember this dissociation in diagnosis (Black and Fourman, 1945). Microscopically, fatty acid crystals, fat globules, and soaps may be seen, but they give little guide to quantitative fat excretion and cannot replace analysis of the stools.

Fat Analysis of Stools.—Analyses done on single stools show great variability. For example, two consecutive specimens so collected produced results of 21% and 36% total fat content respectively. As a routine a 24-hour collection of stools, well mixed, is a minimum procedure. Where progress is to be followed, three-day specimens, well mixed, should furnish the material. This should be done with the patient on a known daily fat intake for at least three days previous to and during collection. The fat-analysis figures given here have been produced by the inadequate present standard methods. Their error is great, and their interpretation must be treated with great reserve. In 10 normals total faecal fat averaged 30% on a diet of 70 g. of fat daily; 20% of cases had faecal fat below 30%. In such cases repeated analysis might have revealed a rise at some time. Clinically these cases differed in no way from others with raised fat in the stools. Conversely, high faecal fat above 50% did not indicate a case of clinical severity. The percentage of faecal fat therefore does not seem to be related to prognosis or to therapeutic response. Duration of steatorrhoea is probably more important. Fat-splitting is excessive in sprue. In the majority of 274 cases the ratio of split to unsplit fat has been between 3 : 1 and 10 : 1; and in 6% it was over 30 : 1. This high ratio may be interpreted as due either to delayed absorption or to excessive lipase action.

Fractional Test Meal.—Hyperchlorhydria or normal acid curves were present in 66% of cases. In a further 27% hypochlorhydria (less than 10 units HCl) was present: this group includes those with apparent achlorhydria. No histamine was available.

Blood Changes.—Table III shows the blood changes. Severe anaemia has not been common even in the clinically severe cases, though the type with "blood crises" has been seen

several times. These cases respond dramatically and permanently to one transfusion. Haemoglobin of less than 12 g.% was present in only 24% of cases. Age of patients and short duration of disease probably account in part for this. At a haemoglobin value of 12 g.% the M.C.H. is minimal 29.5. Variation in either direction shows a rise in M.C.H. It appears that as the anaemia increases it becomes progressively more hyperchromic, and that on recovery this tendency remains.

Blood-sugar Curves.—Few curves have been done in these cases; those of severe cases have shown normal fasting values with low rise as described by Thaysen and Fairley.

Treatment

The object of treatment has been to make the patient fit to travel, not to complete a cure. Criteria of successful treatment have been: (1) ability to take an ordinary hospital diet; (2) stools normal in number and appearance; (3) weight restored to within 10 lb (4.5 kg.) of normal; (4) distension nil, or slight only. Only 31% of our cases reached all these criteria—an index of the number needing further treatment on arrival in England. Treatment has been orthodox; principles only will be mentioned.

Diet.—The high protein, low fat, low carbohydrate diet designed by Hamilton Fairley (1930) has been adopted. A series of five diets in ratios of protein 1, fat 0.5, carbohydrate 2, compiled by Napier (1943), have been used as a basis. Diet 4, with P. 168 g., F. 69 g., C. 235 g., Cals. 2,237, has been most commonly used. All mild cases can take it. When one realizes that milk diets (Manson), high carbohydrate diets (Collin), pure fruit diet (Van der Berg), have all been successful in sprue, one is inclined to ask, What is the principle of dieting in sprue? Constancy and regularity of diet are important in themselves. Any increase, particularly of fat or meat is often followed by a relapse. Liver, marmite, yeast, and bananas are included in the diets for possible therapeutic effects. Vitamins added have been nicotinic acid 50 mg. t.d.s. and riboflavin in some cases. Low fat diet is undesirable since it excludes fat-soluble vitamins. Evidence of K-deficiency has been attributed to unwise fat restriction.

Bed Rest.—This is as important in sprue as in peptic ulcer and should be enforced until diet 4 or equivalent is taken. Fatigue often precipitates relapse.

Parenteral Liver.—Unnecessary in most mild cases, parenteral liver (crude Indian preparation, assayed in England) is useful in all severe cases. The dose used has been 10 c.cm. i.m. for four days, followed by 4 c.cm. i.m. every two days.

Relapse.—(a) *Mild*:—Usually a return to previous diet on the scale, with bed rest, is sufficient. (b) *Acute*:—The sudden onset of 15 to 20 stools a day destroys very rapidly the benefit of weeks of dietetic discipline. Response to sulphaguanidine in the usual dosage, up to a total of 70 g., is almost always good. Sudden anaemia indicates whole-blood transfusion, but with severe dehydration plasma or saline is also indicated. Parenteral nicotinic acid, liver, and cortine have been used on these occasions.

Response to Therapy.—Though immediate response is good many patients have left India showing one or more of the four signs of therapeutic failure: (1) One or more fluid or pale stools daily; (2) distension; (3) weight more than 10 lb. below normal; (4) capacity for sprue diet 5 only. These signs indicate that remission is not complete. It is hoped that they have disappeared in England.

Prognosis

Immediate prognosis for life is good. No patient in the 60 of this series has died. Four deaths have been heard of during three years. Prognosis as regards function on returning to England is not known, but of 40 cases followed up for one year six have had severe relapses, and the remainder less severe recurrence of symptoms. None have been quite well (Lieut. Col. Elder, personal communication). This information is depressing. It is hoped that a fuller survey will be less so.

It is apparent that, in the absence of knowledge as to the essential pathology of sprue, our methods of management and treatment are not curative. Even liver, nicotinic acid, and riboflavin ameliorate only.

TABLE III.—Blood Pictures (250 Cases) (Grouped according to the Hb Level)

Hb Group		% of Cases	Av. Hb (g. %)	Av. R.B.C. (M/c.mm.)	M.C.H. ??
%	G. %				
45-52	7-8	2.8	7.7	2.3	33.5
52-58	8-9	2.8	8.6	2.6	33.1
58-65	9-10	4.0	9.9	3.1	31.9
65-71	10-11	5.6	10.9	3.3	33.0
71-78	11-12	8.4	11.8	4.0	29.5
78-84	12-13	17.3	12.7	4.0	31.8
84-91	13-14	24.9	13.7	4.5	30.4
91-97	14-15	20.9	14.7	4.6	31.9
97-104	15-16	13.3	15.5	4.8	32.3

Summary and Conclusions

The sprue syndrome has been modified by war conditions in India, bringing into prominence certain aetiological and clinical features. Such aetiological points are (a) There is a marked seasonal incidence reaching its peak in the month of June. (b) The condition is prevalent in Assam, North Burma, Bengal, Bihar, and less so in Bombay Presidencies. Whether military or geographical factors have predominated in this incidence cannot be stated. (c) There is a surprising lack of positive relationship with dysentery regarding the monthly incidence and the incidence of dysentery previous to sprue, which is not greater than in normals, but one still retains the impression that in individual cases dysentery may unmask the latent sprue syndrome. (d) Suppressed or latent malaria exacerbates sprue. In such instances eradication of malarial infection rapidly improves the sprue syndrome. (e) A fair or a dull complexion bears no relation to the incidence of sprue, but fair men form a majority of severe cases. (f) Acute sprue has developed on a well balanced diet under jungle warfare conditions. Palatability of diet is as urgent a physiological need as calories.

The clinical picture of acute sprue has been contrasted with that of the classical disease, not often seen in this series. The syndrome following dysentery and subacute hepatic necrosis is described, and emphasis laid on the borderline cases with ptylosis or stenterotheca dissociated.

The complete pictures of vitamin deficiency syndromes have not been met with. Signs of A-deficiency were equivocal. Nicotinic acid deficiency has been more frequent than riboflavin deficiency. No evidence was found of deficiency of vitamins B₁, C, D, and K.

Faecal Fats—The methods of collecting stools at present standard are inadequate. Three day collections on known fat diet, with quantitative measure of stool fat per day, are essential for accuracy. The degree of stenterotheca has little prognostic value.

Blood changes have rarely been severe. With the haemoglobin less than 12 g %, hyperchromic anaemia was more frequent.

Prognosis as to life is good, but as to function it is poor. There is reason to believe that a large percentage will progress into the chronic form unless liver therapy is continued.

From the above description it is clear that in sprue the whole alimentary tract from lips to anus is affected—the accent of the process falling on different regions at different times. We are entirely ignorant of the nature of this process, though we know it to be modified by liver, nicotinic acid, and riboflavin. Nor are we well informed as to the nature of the dysfunctions in digestion and absorption in this condition.

The frequency of remission and relapse and the dissociation of signs and symptoms make assessment of diet or drug therapy very difficult. Many more controlled observations are needed, and until these are forthcoming theorizing on sprue is like trying to do a jigsaw puzzle without most of the pieces.

Our thanks are due to the Director of Medical Services, India, for permission to publish this paper.

The University Extension and Tutorial Classes Council, in co-operation with the Provisional National Council for Mental Health, is prepared to hold this year, provided sufficient applications are received, a course on educationally subnormal children and mental defectives. It is hoped that the course can take place, as in recent years, at the London School of Hygiene and Tropical Medicine, Keppel Street, Bloomsbury, and the date fixed is March 25 to April 5. Students will be required to arrange their own residence. The course is intended for medical practitioners, more especially those who are engaged as school medical officers and as certifying officers to local authorities under the Mental Deficiency Acts. Registration fee 10s. 6d., fee for course £5 15s. 6d. Intending candidates should apply at the earliest possible date, but in any case by Feb. 28. The registration fee must be paid at the time of application and the fee for the course before March 16. If applicants withdraw before this date the fee of £5 15s. 6d. will be returned or carried forward to another course as preferred. Should the course have to be cancelled all fees will be returned. Cheques should be made payable to the Provisional National Council for Mental Health, and crossed Barclays Bank Ltd. All communications with reference to the course should be addressed to Miss Evelyn Fox, C.B.E., c/o University Extension Department, University of London, 39, Queen Anne Street, London, W.1.

OUTBREAK OF WEIL'S DISEASE IN THE BRITISH ARMY IN ITALY

PART I CLINICAL STUDY

PART II POST-MORTEM AND HISTOLOGICAL FINDINGS

BY

H. L. SHEEHAN, M.D., D.Sc., M.R.C.P.
Colonel, R.A.M.C.

(Abridged)

PART I

CLINICAL STUDY

Weil's disease was first proved to be caused by the *Leptospira icterohaemorrhagiae* by Inada, Ido, and others, in Japan, in November, 1914. Cases were described among British troops fighting in the rat-infested trenches of the Western Front (Dawson and Hume, 1916; Stokes, Ryle, and Lytler, 1917). Between the wars the disease was shown to be prevalent in certain parts of Great Britain among fish workers (Davidson and Smith, 1939), sewer-workers, and others. About 25% of rats appear to be infected with the *Leptospira* even in areas where the disease rarely appears (Hurst, 1941). During the recent war the disease has not been common among British troops, presumably because static trench warfare has not been a feature. An outbreak in the British Army in Normandy has been recorded by Bulmer (1945).

The outbreak described in this paper occurred in Italy among soldiers who had all been bathing in the River Arno and its tributaries and in bomb craters, which were just behind our forward positions, during August and September, 1944. The majority of the cases (17 undoubted cases and 2 probables) were dealt with by this military hospital.

Clinical Picture

All the 17 undoubted cases ran a similar course. Onset was sudden, with general weakness, shivering and high fever, nausea, and sometimes vomiting. Severe headache was common at onset, although in some cases delayed for 24 to 36 hours. General muscular aching and stiffness commonly developed with progressive severity over the course of the next few days, sometimes rendering the patient incapable of unaided movement, and in a few cases requiring morphine for relief. This severe pain decreased when jaundice developed. Neck stiffness was complained of in 3 cases.

Intense conjunctival suffusion with a typical varicosity of the arterioles was constant and early in appearing, and tended to persist until the patient began to improve. Icterus developed between the 3rd and 8th days of the illness, in all but one mild case rapidly became very deep, and in every case had a remarkable orange-yellow tint, this colour presumably being due to jaundice in a skin flushed by general arteriolar dilatation. The icterus persisted for weeks, and assumed a more greenish colour as conjunctival and skin suffusion disappeared. Profound anorexia and distressing vomiting characterized the early icteric phase. Tachycardia was marked.

Haemorrhages were seen in every case in this series, varying in degree and situation. Haemorrhagic herpes occurred in 9 cases; petechiae and ecchymoses of skin and mucous membrane were invariably found; subconjunctival haemorrhages and epistaxes were common, and small pre-retinal haemorrhages were observed in 3 cases. Visceral bleeding—in one case frank haematuria—was common, and its severity was a factor in causing death in 5 fatal cases.

All the cases began with high fever (103–105° F.), which settled by rapid lysis as a rule. The duration of the fever, which was unrelated to the severity of the illness, was 5 to 12 days, save in one case in which it persisted for 26 days.

A striking feature of the illness, common to all cases and appearing at about the onset of the icteric phase, was some degree of oliguria; in 3 of the fatal cases and in 2 others this became anuria for a variable period. The urine contained a large quantity of albumin; granular casts and red blood cells were common microscopical findings. Specific gravity tended to remain constant at about 1010, and the amount of bilirubin was less than would have been expected from the severity of the jaundice. During this ictero-oliguric phase extreme prostration, mental torpor, and quiet delirium were the rule. During this phase also the blood urea figures were raised considerably (save in the one mild case). Death occurred in 5 cases between the 7th and 14th days of illness—in four from uraemia and in one from uraemia and massive pulmonary haemorrhage.

The spleen was palpable in 1 case and doubtfully so in 2 others. Hepatomegaly was inconstant and never great. Polymorphonuclear leucocytosis occurred in all save the one mild case during the acute stage of the disease.

Treatment

Specific therapy employed was penicillin in 6 and antileptospiral serum in 3 cases. When the first cases were diagnosed the only information available was that *L. icterohaemorrhagiae* was insensitive to penicillin *in vitro* (Abraham *et al.*, 1941). It was decided, however, to use penicillin in "orthodox" dosage and await results. The dosage in the 6 cases was 15,000 units three-hourly by the intramuscular route to a total of 600–660 thousand units. Unavoidably penicillin could not be started in the pre-icteric stage, but between the 6th and 10th days of illness. One patient treated on the 7th day died after 210,000 units. Five cases recovered after illnesses of great severity, not differing from those which did not receive specific treatment. The absence of any obvious benefit on the fever, toxæmia, icterus, pulse rate, or urinary output discouraged us from using heavier doses of a drug then scarce. Antileptospiral serum, also scarce, was used in 2 cases in doses of 60 c.c.m. intravenously on the 7th and 8th and the 6th and 7th days of illness respectively, with 1 death; and in the third case, also fatal, 60 c.c.m. was given only on the 7th day of illness. The serum had no obvious beneficial effect. In 8 cases (2 fatal) no specific therapy was used.

General measures were directed towards combating liver and renal failure. Fluids with added glucose were pushed by mouth, heavy doses of alkali given orally, and intravenous drip infusions of 3.3% glucose in 0.3% saline used as a routine. The impression was formed that unless oliguria can be rapidly abolished a fatal outcome is certain in this disease.

Laboratory Findings

[Here the authors acknowledged the help of three laboratories—No. 1 Central Pathological Laboratory, the Emergency Vaccine Laboratory U.K., and the laboratory of the British Traumatic Shock Research Team.]

Guinea-pigs were inoculated intraperitoneally with 5 c.c.m. of blood taken from 15 of the cases on the 3rd to 11th days of illness, and with 10 c.c.m. of urine (alkalinized) from the other 2 cases on the 13th and 16th days respectively. Eleven of the guinea-pigs remained well; the other 6 became ill, and of these 5 died, and at necropsy showed to a varying degree jaundice, haemorrhages into the abdominal viscera and retroperitoneal tissues, and the characteristic "butterfly" haemorrhage in the lungs. *Leptospira* were grown from the kidneys of 3 of them. From 13 of the 17 cases in this series serum was examined for leptospiral agglutinins, some being tested against local "Cartwright" strains, some against stock "Winjberg" strains, and some against both. No serious antigenic difference between the strains was demonstrated. All the sera gave a "positive" result at a conservative diagnostic level of titres of 1/300.

Total leucocyte and differential counts were carried out on all 17 patients between the 4th and 8th days of disease. A leucocytosis ranging from 11,000 to 34,000 per c.mm. was found in 10 cases; 5 in which the counts were below 10,000 reached levels of 13,000–20,000 by the 9th to the 15th day. In 12 of

the 17 cases a blood urea estimation was carried out between the 5th and 15th days, and in 8 the figures obtained ranged from 150 to 288 mg. per 100 c.c.m. There was evidence of some degree of nitrogen retention in all cases. The value of guinea-pig inoculation and the estimation of leptospiral agglutinins, total and differential leucocyte counts, and blood urea in the diagnosis of Weil's disease is amply supported.

Convalescence

Convalescence was slow in each of the 12 patients who recovered, and they were not considered fit for discharge to a convalescent depot until 17 to 20 weeks from the onset of their illness. During the convalescent period a series of investigations were made in an attempt to judge progress and to determine whether or not there was any permanent hepatic or renal damage.

With the exception of the one comparatively mild case, all showed a degree of anaemia. During the 4th week haemoglobins ranged from 70 to 80% (Haldane), with total red cell counts of between 3.5 and 4.5 millions per c.mm. This anaemia responded very slowly to iron therapy. The polymorphonuclear leucocytosis of the acute stage of infection disappeared during the 3rd and 4th weeks, and a total count below 10,000 per c.mm. with a relative lymphocytosis was common to all cases during the convalescent period. Sedimentation rates of between 20 and 40 mm. in 1 hour (corrected Wintrobe) were observed in all cases up to the 8th week, and figures of under 10 mm. were not encountered until the 10th week, thus confirming the slowness of convalescence.

Urea concentration tests were carried out between the 8th and 11th weeks of disease. In all but 3 cases a normal concentrating power was observed, and in these 3, on repeating the test later, the concentrating power was found to be satisfactory. Thus there was no evidence of gross renal damage as judged by the only renal function test readily available in the field. Hippuric acid liver function tests were carried out between the 8th and 15th weeks, and all but one case (and that case also on a later repetition of the test) gave results within the normal range. This again was the only suitable test available under field conditions, and showed no evidence of serious impairment of liver function.

Discussion

The 17 cases were all examples of the haemorrhagic form of the disease, and all but one were severe. Few diseases simulate the clinical picture outlined.

[Here the authors described other cases admitted to the wards in which the possibility of Weil's disease had to be seriously considered.]

During the period when the Weil's cases were in the wards over 1,800 cases of infective hepatitis were seen; but in only a very small minority, with fever, muscle-aching, conjunctival suffusion, and occasional neck rigidity, was Weil's disease really simulated, and it was felt that the possibility of confusion between Weil's disease and infective hepatitis is remote.

It is probable, however, that even severe cases of Weil's disease may occasionally run an atypical course. Such a case was one of two "probables" in this outbreak, in which the diagnosis was thought to be enteric fever with jaundice until, after the patient's recovery, the leptospiral agglutination results became available and the patient's serum taken on the 13th and 23rd days of illness showed a rising titre from nil to 1/1000 respectively. Such a case illustrates the difficulties which may confront the clinician in a country where Weil's disease, enteric fever with jaundice, malaria with jaundice, infective hepatitis (and even amoebic hepatitis combined therewith) may all occur at the same time.

The occurrence of non-icteric cases of Weil's disease has been recognized in previous outbreaks (Davidson and Smith, 1939); attention was called by Bulmer (1945) to the existence of such undiagnosed cases in the Normandy outbreak. The recognition of non-icteric cases depends on two factors: the suspicion that cases of P.U.O. may be instances of this disease, and the conversion of that suspicion into a certainty by serum agglutination reactions. The second "probable" case in this series, the diagnosis of which was not made until long after the patient's return to duty, was suspected because of the excessive severity of muscle-aching, a seven-day fever with one spot of herpes

PRIMARY TUBERCULOSIS IN CHILDHOOD*

BY

WILFRID F. GAISFORD, M.D., F.R.C.P.

Consulting Paediatrician to the Warwickshire County Council
Hospitals

The problem of tuberculosis in infancy and childhood—especially in infancy—is still far from being solved. The British Paediatric Association published a report (1943) on "The Early Diagnosis of Intrathoracic Tuberculosis in Childhood," and this report gave rise to considerable criticism on the part of the various tuberculosis organizations. Arising out of this a joint meeting of the Tuberculosis Association and the British Paediatric Association was held, and, in spite of the friendly spirit evident, it was clear that each party viewed the problem in an entirely different light. The Tuberculosis Association members quoted figures from their official returns, both of morbidity and of mortality, which were totally at variance with the clinical experience of the paediatricians, and in the main their conclusion was that "childhood tuberculosis is not of great importance to the public health services," and their plea was for the paediatricians to preserve a sense of proportion!

Now, there must be some explanation for this divergence of views about both the incidence and the importance of the condition. Are paediatricians wrong in stressing the matter as they do? Are they making too much fuss about something of less importance to the community than adult phthisis? I do not think so. Anyone working among children, and particularly in children's hospitals, and seeing the scores of infants dying of tuberculous meningitis must realize the gravity of the situation, considering that the majority of such infants die within three months of their initial infection and that every year thousands of infants and children are infected by phthisical adults. Although the majority pass through their primary infection and are none the worse for it, and although only a very small proportion progress to tuberculous meningitis, yet there is much pain and illness due to bone, joint, and kidney disease following a primary infection, as the records of any children's hospital will show.

It is interesting that the American public health administrators take a view similar to that of our tuberculosis authorities. Plunkett (1939) estimates that it costs 40 times as much to find a case of childhood tuberculosis as it does an adult case, and he therefore recommends investigating only children from known tuberculous households—which is what obtains generally in this country. Nelson (1942) says, further: "One must recognize the necessity of being selective in the expenditure of the efforts of public health agencies and the need for directing activities into the channels which will be productive of the greatest good to the general population."

Why is there this divergence of views? I think the tuberculosis officers do not get a fair view of the picture as paediatricians see it. Many cases are missed: many more are never seen by the tuberculosis officer; they are sent direct into hospital or to the out-patient department, and there their notification is either intentionally or inadvertently overlooked. Few convalescent homes will admit cases of tuberculosis even though they are certified as non-infective, as most of them are, and prolonged convalescence is an integral part of their treatment and it is unwise for them to go to sanatoria, where there is a risk of their coming into further contact with open tuberculosis. Furthermore, from a practical point of view, it would be impossible for tuberculosis officers, under existing conditions, to deal with all the cases, even if there were adequate accommodation.

Diagnosis

Primary tuberculosis is important because it is the commonest manifestation, because it is often difficult to diagnose, because it most easily leads to the tracing of the adult infector, and because when adequately treated it gives excellent results. As is well known, it is usually intrathoracic and due to direct droplet infection or, in the case of crawling infants, to infected dried dust from the floors or carpets of a house where a phthisical adult lives.

The ordinary symptoms of adult tuberculosis—cough, fever, night sweats, loss of weight, sputum and haemoptysis—are not common symptoms in primary tuberculosis in infants or children.

Cough.—Excluding children ill with bronchitis, pneumonia, and whooping-cough (and remembering that many children with primary tuberculosis are not ill when first seen) the commonest cause of cough in childhood is upper respiratory infection—especially tonsillar.

Fever.—The commonest causes are upper respiratory infection (including otitis) and pyelitis, both especially common in infancy. There is an "initial fever of infection" in primary tuberculosis which lasts for a week or ten days and is usually overlooked or considered influenzoid in nature. It is seldom of diagnostic value.

Night Sweats.—These are rare in children: they do not occur in primary tuberculosis. In infancy, rickets, digestive disorders, pyelitis, and pink disease may be causative.

Loss of Weight.—This occurs in many nutritional disorders in infancy and is of no real help in arriving at a diagnosis of primary tuberculosis.

Sputum.—Children rarely expectorate, except occasionally in bronchiectasis, and haemoptysis is even rarer. Neither of these is a symptom of primary tuberculosis.

In fact, the condition is often subclinical throughout, and there are no characteristic physical signs which can be considered pathognomonic.

Erythema nodosum and phlyctenular conjunctivitis are two commonly encountered conditions in paediatrics, and they are both very suggestive of primary tuberculosis. The younger the child the more likely are they to be tuberculous. They are not in themselves tuberculous, but are manifestations of tuberculin allergy. Erythema nodosum may occur in rheumatism, cerebrospinal fever, and as a sign of sensitivity to sulphathiazole; but by far the largest number of cases occur in primary tuberculosis, and it has been called "the exanthem of tuberculosis." It usually marks the onset of allergy at the end of the incubation period.

X rays are of value in the diagnosis of primary tuberculosis, especially serial films, as there are few other causes of persisting abnormal lung shadows in childhood.

The tuberculin test is the only sure diagnostic test. It is impossible to diagnose primary tuberculosis with certainty without its use (except by actually finding tubercle bacilli—as, for example, in stomach washings). Often it is the only positive finding at the time of examination, and further confirmation may not be forthcoming for months till skiagrams reveal a parenchymal or glandular lesion.

As a routine a preliminary percutaneous test (jelly, ointment, or plaster) may be used, but if this is negative a Mantoux test must follow before tuberculosis can be definitely excluded. The technique of intradermal injection is so easily acquired, however, and, properly performed, so little upsetting to children, that the Mantoux test still remains the method of choice as a routine. For infants and children it is safe to use 0.1 c.cm. of 1 in 1,000 old tuberculin (i.e., 0.1 mg.), except in cases of erythema nodosum and phlyctenular conjunctivitis, which are generally hypersensitive and in which a 1 in 10,000 solution should be employed. If the 1 in 1,000 solution gives no reaction and there is still doubt about the possibility of tuberculosis, then a 1 in 100 solution may next be tried, and if this too is negative a 1 in 10 solution. If there is no reaction to this the child (unless moribund) is not suffering from tuberculosis. Once a child is known to be Mantoux-positive, the fact should be noted in his record in the same way as his Schick test, immunizations, etc. It has been said, "If 100% be allotted to the Mantoux test in the diagnosis of primary tuberculosis, then x rays earn 25% and physical examination a fraction of 1%."

Of course, finding a positive reaction does not mean that the child is necessarily suffering from tuberculosis, but it does mean that he should be further investigated—first by skiagrams; if these show any abnormality a blood sedimentation test may give some indication of activity, and gastric lavage and guinea-pig inoculation may yield confirmatory evidence.

Treatment

If the sum total of these investigations confirms the diagnosis of primary tuberculosis, what is to be done with the child? The most important thing is rest in bed until the blood sedi-

* Abridged from an address delivered to the York Medical Society, Oct. 20, 1945.

mentation rate is normal and skiagrams show evidence of healing or the lesion appears quiescent, then fresh air, good food, adequate amounts of vitamins A, C, and D, and not too much fat and "malt and oil," which are often given to the detriment of the appetite.

There is abundant evidence that repeated exposure during the initial period after infection tends towards severe disease and liability to military spread. Therefore children, and especially babies, should be carefully watched for three months until the likelihood of meningitis is passed, and should be separated from any known contact. If a home contact must persist—e.g., the parent cannot go to a sanatorium—then the infant should be sent to a preventorium, where special care should be taken to avoid exposure to, or have immunization against, epidemics such as measles and whooping cough.

There is, again, ample evidence that breaking the contact materially lessens the mortality and morbidity. Children with erythema nodosum need careful watching—being "hyper-allergic"—and should have bed rest for six weeks after which time the chance of dissemination is less. After the period of bed rest the children should be allowed up for increasing periods daily and be permitted exercise also. School-children are preferably allowed to run wild for a term if reasonable hygienic conditions prevail at home and they can have plenty of fresh air.

Finding a positive reaction in a child—for example, by routine testing—does not involve an immediate diagnosis of active tuberculosis: a warning to the parents of possible meningitis, notification to the tuberculosis officer, and so on, but it does involve a little extra work. Park says, "There are two ways of finding out if an adult has tuberculosis: one is to find the bacilli in his sputum—the other, the infection in his infant. Under the age of 2 years over 80% of infections are intra-familial in origin, so the parents and other members of the family (including nurses and maids, if any) should be examined and x-rayed. At school age the contacts are so many and varied that it is manifestly impossible to trace them all."

What is the Fate of the Primary Infection?

Either spontaneously or with treatment it may undergo fibrosis and calcification and heal completely. This is usual. Untreated, it may proceed to caseation in the primary focus, bronchogenic spread, glandular spread in the hilum, or blood spread with resultant metastases. The site of these depends on the vessel involved and the number of bacilli entering the circulation. If a branch of the pulmonary artery is involved military tuberculosis results, if the pulmonary vein either meningitis or, if only a few bacilli enter, isolated bone or kidney metastases. If the glands caseate and discharge into the thoracic duct both lung and systemic spread may occur.

Clinical Importance of the Primary Infection

A healed primary lesion does not confer complete immunity to reinfection, but partial immunity may result, with ability to withstand heavier infections or to cause greater localization of lesions. This limited immunity can be overcome by vast or virulent infection. Immunity takes some time to develop, perhaps 12 to 24 months. Wallgren says that, after immunity is developed, further exposure to infection is not harmful. There are two schools of thought about the importance of the primary infection—one that it is benign but that the resulting allergy is dangerous, the other that allergy is beneficial. Wallgren goes so far as to recommend vaccination with BCG. The relationship, if any, between allergy and immunity is not known.

Immediate Dangers of the Primary Infection

The majority of cases quiesce, but age is the important factor. The death rate is higher in the first two years of life than at any other period of childhood, because of lower resistance and greater and more repeated exposure (due to the intra-familial nature of the infection). Wallgren (1941) found a mortality of 36.9% in the first year of life, and Price (1942), in Dublin, of 77% in 1937, reduced to 28% in 1940 after instituting routine tuberculin-testing in the newborn on the district and treating the positive reactors in preventoria. Terplan (1940), in doing 699 routine necropsies, found 35 deaths from tuberculosis, of which 30 were due to primary

tuberculosis. Mitchell and Willis (1944) treated 213 children under the age of 3 for a year or more, with a 9% mortality and Salomonsen and Traetteberg (1935) in a ten-year follow-up found a mortality of 4%. The conclusion is that, given adequate treatment for a sufficiently long period, the prognosis is excellent.

Extrathoracic Foci of Primary Infection

The alimentary tract is the chief site. Infection follows ingestion of bacilli, either human from dried dust or bovine from milk. The primary focus is in the ileum in the region of Peyer's patches, and the complex is completed by the mesenteric gland draining that area. As in other extrathoracic foci, the primary lesion is usually microscopic. The tendency is for the lesion not to localize as well as a primary pulmonary focus, and there is a danger of meningitis by rupture of the caseating mesenteric gland into a mesenteric vessel. Normally the gland calcifies.

I have seen one case of primary tuberculosis of the skin following ritual circumcision, the complex being completed by the inguinal gland. The tonsil is sometimes a primary site (as in the Lübeck disaster), and the cervical gland on the affected side then becomes involved.

Some Practical Points

Lastly, a few practical considerations concerning childhood tuberculosis in general (i.e., not limited to the primary form).

Watkins (1945) in Cardiff, working in a children's ward which specifically excluded cases of tuberculosis, discovered by routine Mantoux-testing that 22% of the children admitted reacted positively, and that 2.2% of these had in fact, active tuberculosis. The presenting signs and symptoms of the intrathoracic cases were bronchitis and pneumonia, pleural effusion, wasting, erythema nodosum and phlyctenular conjunctivitis, and diarrhoea.

Capon (1937) working at Alder Hey Hospital, Liverpool, reported 56 cases of active tuberculosis among 200 children tested there (partly selected), with almost identical presenting symptoms.

What symptoms bring a child up to the out-patient department with the diagnosis "tuberculosis," and from what is the child really suffering? I have found the commonest conditions to be: (1) cough, (2) glands in neck, (3) diarrhoea especially if with a swollen belly, (4) limping, (5) swollen joints, (6) fever.

Cough—This is most commonly due to upper respiratory infection. Post-pneumonic fibrosis, with or without bronchiectasis, is an occasional cause.

Glands in Neck—Dirty heads, impetigo and tonsillar and oral sepsis predominate. Cystic hygroma and secondary malignant glands occur rarely, but I have seen examples of both which needed differentiating from tuberculous glands.

Diarrhoea—Rickets, Hirschsprung's disease, coeliac disease, and cystic fibrosis of the pancreas will all cause diarrhoea similar to that occurring in *tabes mesenterica*. The last named is perhaps the commonest, and many of the cases labelled coeliac disease really belong to this group; they are differentiated from them by having less buttock wasting, by having recurrent attacks of pneumonitis, and by clubbing of the fingers. *Tabes mesenterica* is even more to the fore in differential diagnosis as if the lacteals become blocked in *tabes*—as they may from glandular pressure—the faeces become pale, foul, and fatty just as in pancreatic fibrosis.

Limping—I think tuberculin-testing finds some of its greatest usefulness in orthopaedic cases. Lincoln has said "The onus is on anyone making a diagnosis of tuberculosis in any child with a negative Mantoux unless the child is moribund."

Swollen Joints—or usually *One Swollen Joint*—Tuberculous joints must be differentiated from rheumatism without carditis, Still's disease, and "tuberculous rheumatism." The Mantoux test is more valuable than skiagrams in joint disease, in cases of doubt. *Tuberculous rheumatism* is an allergic arthralgia rather than a true arthritis—not responding to salicylates, not having carditis, and having a positive Mantoux. It has been described chiefly in the French literature, but Sheldon (1945) recently reported a series of cases in this country.

Fever Especially Continued Fever of Unknown Origin—Urinalysis, a differential white blood count, and blood agglutinations will often clear up the diagnosis. A negative Mantoux with 1 in 100 will exclude tuberculosis as a cause.

Among in-patients the commonest diagnostic difficulty is probably differentiation between appendicitis and tuberculous

mesenteric glands. Here, to wait for the result of the Mantoux test is impracticable, and in cases of doubt the surgeon will always operate. If he finds a tuberculous adenitis no harm will be done, and an opportunity will be afforded for testing the potency of a new bottle of tuberculin on an undoubtedly positive case!

Conclusion

I may conclude by quoting a remark of Nelson's. He said: "One of the shortcomings of the average general practitioner is his failure to recognize the relationship of his private practice to the general health problems of the community. The ideal procedure would be for him to do tuberculin tests on all children under his care and order x rays on all positive reactors and their contacts." If we could get this far we should at last really be on the way to solving the problem of primary tuberculosis in childhood.

INTELLIGENCE AND INFANT MORTALITY IN PROBLEM FAMILIES

BY

S. W. SAVAGE, M.D., D.P.H.
County Medical Officer, Herefordshire

The objects of the investigations described in this paper were:
(1) To discover the number of problem mothers in an area which was predominately rural, with a population of 90,800.
(2) To ascertain the intelligence of these problem mothers.
(3) To discover the effect on the development of children living in the inefficient domestic environment made by the problem mothers and to compare them with children from normal homes (controls). This is of great interest when the intelligence of problem and control mothers is the same. (4) To examine the rate of infant deaths occurring in problem and control families.

A "problem mother" is a woman who does not give her children at least the minimum of care and refuses to co-operate with the health visitors and make effective use of the technical advice available to her. The fathers have not been included in the investigation; but it is not denied that their influence on the children is considerable (though probably less than the mothers').

The problem families were detected through the affected children. These children became known through the school medical officers, the health visitors, and the school nurses. Children were sometimes reported from other agencies such as the N.S.P.C.C. In all these cases the homes were visited and the mothers instructed by the health visitors. When the mothers persistently failed to take advantage of this teaching and continued in their inefficient domestic practices the family was recorded in the problem group. Whenever there was any doubt about recording a family in the problem group a special visit was made by the supervising health visiting staff. In the course of the survey I have personally visited most of the families. In these ways a uniform standard was preserved.

For the purposes of this survey it was necessary to make a comparison with a number of families whose domestic management was at least moderately efficient, and who lived under the same general economic standards as the problem families. These were the control families; they were selected by the health visitors. The standard of housing of both the problem and the control families was similar. There is room for improvement in some of the houses in both groups. Most of the families under review come within the Registrar-General's Social Class V. Although the whole summary took many

months the records were kept completely up to date; the following tables therefore record the position on the day when the survey was completed. The preliminary ascertainment made are expressed in Table I:

TABLE I.—Survey Area

Population	90,800
Number of families with pre-school and elementary-school children	7,215
Number of problem families	89
Percentage of problem families	1.23
Population of pre-school and elementary-school children (7,295 + 10,168)	17,463
Number of pre-school and school children in problem families	333
Percentage of problem family children compared with all children in the area	1.9
Annual infant mortality rate for the area (1944)	38.7
Infant mortality rate for the area during the last 10 years	48.5

The total number of families was estimated from the records of pre-school and school children in a section of the area, and the number in the whole area was calculated from this information.

In my view, one of the most important observations to make in a problem mother is an assessment of her intelligence. When the mother has intelligence there is a possibility of teaching her by detailed and persistent instruction, but with an intellectually defective mother improvement is almost impossible. Intelligence can be estimated in various ways, but after an investigation of many tests the Raven progressive matrices were chosen as being most suitable for assessing intelligence in people who may have very little general education but may nevertheless be reasonably intelligent. It will be seen from the tables that the Raven test makes use of five-grades. Some of the testing was carried out by specially selected health visitors and some by myself. The selected health visitors were first tested and then instructed.

Comment on Table II

The problem families (89) were classified according to the type of neglect found in the children. By far the most were in Group I, "general neglect"; there were a number of families in which the children suffered from persistent pediculosis capitis and in which the general neglect was less obvious than the pediculosis (Group II). When the general neglect was also very marked they were placed in Group III. The feeding of all these children was usually unsatisfactory, but when this was obviously bad and the children also suffered from pediculosis the families were placed in Group IV. The average age of the school-children in problem and control groups was similar (it is recorded in detail in Table III).

The educational position of all the school-children is shown. This was obtained by reports from the head teachers. The percentage of those retarded two or more years has been also calculated. Objection might be made to the use of the educational attainment as an index of intelligence, but means were not available for carrying out tests such as the Binet-Simon on the 409 school-children. It will be observed that those in the problem families were very considerably retarded. In all problem groups a proportion of the children were retarded sufficiently to bring some of them within the mentally defective classification. Of the 223 children 55 (24.6%) were retarded three or four years, and if the children of only two years' retardation are also included, almost 50% of the school-children from the problem families were retarded. The corresponding figure for the control children was 9%.

This retardation was highest (65%) in the children suffering from pediculosis and an inadequate diet (Group IV), and lowest (37%) in the children who suffered only from persistent pediculosis (Group II). It is interesting to note that the only children described by the head teacher as "advanced one year" came from the group with the highest percentage of retarded children. These children have had school meals, but so have some of the other children in families known to have had an inadequate diet.

The infant mortality rate in the problem families was double the rate in the control families. In the problem families the highest infant mortality rate occurred in the "general neglect" group. The numbers in Group IV were insufficient for a reliable rate to be calculated.

TABLE II.—Classification according to Type of Neglect

Type of Neglect found in the Children	Number of Families	Number of Children				Educational Position of Children										Mother's Intelligence						Infant Deaths 1 Year	Child Deaths 1 Year	Total Births	Infant Mortality Rate
		Pre-school	School	Left School	Total	Advanced (Years)		Normal	Retarded (Years)				Percentage of School Children 12 Years or Over	Mentally Superior	Above Average	Average	Below Average	Intellectually Defective	Refused Test						
						2	1		1	2	3	4													
General neglect (Group I)	46	74	103	31	203			25	22	27	14	15	54.0			15	18	12	1	17	3	223	74.55		
Persistent pediculosis (Group II)	22	16	57	17	90			20	16	9	9	3	37.0										95	44.67	
Persistent pediculosis and general neglect (Group III)	13	12	40	10	62			12	9	12	5	2	45.5		1		1	3	4				65	88.82

	Problem Control			89	132	186	35	353	—	—	—	117	39	15	2	—	9.1	11	3	367

Comment on Table III

In this table the problem families were classified according to the intelligence of the mothers, whether problem or control. It will be noticed that no control mothers were found to be "intellectually defective" and no problem mothers were found to be "mentally superior" and only two "above average". When these three groups have been excluded, a number of control and problem families whose mothers were in the "average" and "below average" groups can be compared.

For instance, in the families with mothers of "average" intelligence just over 50% of children were retarded two or more years in the problem families, but under 7% of children in the control families. In the families with mothers of "below average" intelligence 45% of the children from problem families were retarded two or more years, while only 12.3% of children from the control families were retarded. The average age of the school-children in the problem and control families is shown, and it will be observed that the ages make the groups reasonably comparable.

The infant mortality rates for the various groups bring out the importance of maternal intelligence. In the problem group where the mothers were intellectually defective the rate was as high as 88.7, and this decreased as the intelligence of the mothers improved. In the control group a similar relation can be observed, although, as would be expected, the infant mortality rate is lower than in the problem families where the intelligence groups are comparable.

Other Observations

A table was constructed showing the cause of infant deaths classified in groups according to the mothers' intelligence. This is not published, as it was felt that the numbers were insufficient

for any reliable conclusions to be made. The number of abortions, stillbirths, and cases of icterus neonatorum have also been recorded, and further observations are being made to correlate these findings with the Rh factor. Experimental intensive domestic instruction is being given by trained domestic science workers to some of the problem families in the "average" and "below average" groups, the effect of this will be observed at a later date.

Summary

The number of problem families and their children have been recorded in a survey area.

The intelligence of the mothers was ascertained, and only 29.2% were found to be intellectually defective and consequently educable.

The most serious detectable change in the children (even when the mothers were of average intelligence) was a very considerable retardation in school, amounting to mental deficiency in some of the children.

The infant mortality rate was shown to be directly related to the intelligence of the mothers. In problem families of the lowest intelligence it was as high as 88.7.

I should like to record my appreciation of the work carried out by the health visitors. The merit of their usual routine work is insufficiently known and valued. In this inquiry their duties were temporarily increased, but they showed great willingness and an understanding of the objects of the survey.

The Minister of Health has sent a mission to study public health administration, particularly hospitals and health centres, in Sweden and Denmark. The leader of the mission is Capt. J. Snow, and the other members are Dr. J. A. Charles, deputy chief medical officer of the Ministry, Mr. S. F. Wilkinson, a principal assistant secretary, and Major D. Bruce, the Minister's Parliamentary Private Secretary.

SPONTANEOUS HAEMOTHORAX

BY

A. MUIR CRAWFORD, M.D., F.R.F.P.S.

AND

J. SHAFAR, M.D., M.R.C.P., D.P.H.

(From the Royal Infirmary, Glasgow)

The recognition of the presence of fluid within the pleural sac offers little difficulty as a rule, but the nature of the fluid as determined by thoracentesis may on occasion prove surprising. Such an instance occurred in the case reported here when, in the absence of a history of trauma, the fluid withdrawn appeared to consist of pure blood.

Case Report

The patient, a man aged 44, a civil servant, was in good health until Aug. 19, 1944. On that date, while riding in a tramcar, he was suddenly seized with pain of knife-like severity in the middle zone of the left side of the chest. Breathlessness developed simultaneously. He was weak and collapsed, and had to be assisted home. The pain remained for several days, gradually decreasing in severity, but the dyspnoea persisted.

He was admitted to hospital eight days after the onset. The general condition and colour were good, but he looked anxious and his respirations were increased, although cyanosis was not evident. He was orthopnoeic, and the adoption of the prone position increased the respiratory distress. The mobility of the left side of the chest was markedly restricted and there was extensive dullness to percussion, reaching as high as the third rib; over this area the vocal resonance and vocal fremitus were reduced and respiratory murmur was absent at the base and greatly reduced at the higher levels of the zone of dullness. The heart was displaced to the right, but a Grocco's triangle was not demonstrable. Examination of the other systems revealed no abnormal features. The B.P. was 120/70. A skiagram taken on Aug. 28 showed evidence of a left-sided pleural effusion; no air was present in the pleural cavity. On Aug. 31 an exploratory puncture of the chest was performed and 10 c.cm. of what appeared to be pure blood was obtained. The haemoglobin content of this sanguineous fluid was found to be 65% (Sahli). The patient's progress was satisfactory, and serial examinations revealed signs of absorption of the fluid. A further x-ray examination of the chest on Sept. 13 showed a diminution in the size of the effusion, which was now seen to extend into the interlobar fissure. Thirty-three ounces (938 c.cm.) of blood-stained fluid was withdrawn on Sept. 20 and a further 16 oz. (454 c.cm.) on the 23rd.

The patient was discharged from hospital on Oct. 11. At that date a dull percussion note could be obtained only at the lowermost zone of the left chest, while the air entry seemed unimpaired. The radiological findings were then those of a residual opacity in the left costo-phrenic angle, which was considered to represent pleural thickening. The patient felt very well and was free of symptoms. During his stay in hospital the pulse and respiration rates and the temperature were raised, but the latter never reached above 100° F. Within three weeks they had settled to normal levels. Examination of the fluid originally withdrawn from the chest showed very numerous red cells and also endothelial, polymorph, and mononuclear cells; bacteriological culture was negative and no tubercle bacilli were found.

A month after his discharge from hospital the patient reported for re-examination, and the only abnormal sign in the chest was a slight impairment of the percussion note at the left lung base. Physical examination on July 27, 1945, revealed no evidence of abnormality in the chest, and a skiagram showed that the left lung field was now clear, only very slight pleural thickening being noted in the costo-phrenic angle.

Discussion

Blood in the pleural cavity may be associated with trauma, neoplasm, infarction of the lung, tuberculosis, severe fevers, chronic nephritis, cirrhosis of the liver, and blood dyscrasias. Among other causes are rupture of an aneurysm of the thoracic aorta or other thoracic vessel, scurvy, caries of a rib, multiple telangiectasis of the pleura, and injury to a blood vessel in paracentesis, thoracoplasty, or other surgical procedure such as division of pleural adhesions. Chandler (1937) also refers to the very rare condition of recurrent and even bilateral haemorrhage of unexplained aetiology known as pachypleuritis haemorrhagica. In the absence of an obvious cause haemorrhage into the pleural cavity is a rare event. The incidence of the so-called spontaneous variety, as judged from the literature,

is very low, although this undoubtedly is an underestimation, since not all examples are reported. Frey (1935) was able to discover only 10 cases. Hartzell (1942) compiled a list of 40, the series including only those who had been personally examined and in whom tuberculosis could be excluded satisfactorily as a cause; he records three additional cases of his own. A striking feature has been the constancy of the age and sex incidence. All the subjects have been men, with the exception of one of the three cases reported by Hopkins (1937). The age of the patient was mentioned in 41 of the 43 cases, and in all but 5 it fell between 20 and 40 years. The examples cited by Davidson and Simpson (1940) and by Lea (1942) were both males 26 years of age, and the case of Almeyda (1943) a man aged 41. There does not appear to be a predilection for either side of the chest.

While spontaneous haemorrhage does not owe its origin to an inflammatory process, the blood acts as an irritant to the serous membrane and a reactionary pleural exudate results. The pleural effusion thus evoked dilutes the blood and adds to the volume of intrapleural fluid. The studies of Sellors (1945) show that in six cases operated upon within a few hours of the injury producing the traumatic haemorrhage, the haemoglobin level was 30 to 40% below that of the circulating blood. Further dilution of the haemorrhagic pleural fluid occurs, so that in some instances the haemoglobin content may be below 20% only four days after the injury. However, there appears to be much variation in the velocity of the fall of the haemoglobin values in different subjects. That the colour alone may give a false impression of its blood content is emphasized by Sellors (1945), since 5 to 10% haemoglobin content may yield an appearance of heavily blood-stained fluid.

Haemorrhage must be distinguished from haemorrhagic pleural effusion and due consideration be paid to the lapse of time between the examination of the fluid and the onset of the condition. Obviously haemoglobin estimation is necessary. It is a well-established fact that blood maintains its fluid state while in the pleural cavity. Clotting does occur as in bleeding from other sites, but the haematoma is rapidly defibrinated by the agitation produced by cardiac and respiratory movements. Eosinophilia is often found in the intrapleural blood, which is of dark colour. The eosinophil cells have been considered to represent neutrophils which have engulfed haemoglobin, but this explanation has been denied by Grabfield (1921).

Tearing of a pleural adhesion in patients receiving therapeutic pneumothorax may result in haemorrhage, but Korol (1936) points out the rarity of haemorrhage in pulmonary tuberculosis considering the great frequency of large haemorrhages and of spontaneous pneumothorax in tuberculosis. He attributes this to the fact that the perforation involves the periphery of the lung, where the blood vessels are small, and to the poor vascularity of the tuberculous or emphysematous tissue which is the seat of the perforation. However, Mazzei and Pardal (1934) showed that subpleural bullae may be richly vascularized. They demonstrated a layer of newly formed vessels with abundant anastomoses which could give rise to large intrapleural haemorrhage. If this be the case, then it is all the more surprising that spontaneous pneumothorax is so rarely attended by the presence of any quantity of blood in the pleural cavity.

The commonest cause of spontaneous pneumothorax is the rupture of a valve vesicle situated on or near the pleural surface. The vesicle may be a manifestation of healed tuberculosis or of localized emphysema. Communication with neighbouring bronchioles by a valve-like mechanism allows the entry of air but hinders its exit, and thus the bulla increases in size and may finally rupture. When rupture does occur bleeding might be anticipated as a concomitant incident, and perhaps its absence depends on the immediate pulmonary collapse, which brings about a retraction of the injured blood vessels as well as slowing of the circulation through the lung. Korol (1936) points out the efficacy of artificial pneumothorax in the treatment of haemoptysis and considers that it is the latter factors which operate. Careful inspection of the skiagram of a case of spontaneous pneumothorax will often reveal a small amount of pleural fluid in the costo-phrenic angle.

It becomes apparent that some additional possible mechanisms must be sought to explain the origin of spontaneous haemorrhage.

thorax. The view of most contributors to this subject is that a spontaneous pneumothorax is the initial event. As the intrapleural pressure rises any pleural adhesions which exist will become stretched and may ultimately rupture, so producing a spontaneous haemopneumothorax. The collapsing lung tears the adhesion which contains blood vessels and the escaping blood accumulates in the pleural cavity. Leopold and Lieberman (1935) at necropsy found pleural adhesions in almost 50% of all individuals above the age of 20, even after eliminating all cases with a history of acute or chronic pulmonary disease, in many cases these adhesions contain large blood vessels which carry an arterial pressure six times that of the pulmonary circuit. Examples are on record which clearly demonstrate a pneumothorax preceding the haemorrhage, Rist and Worms (1940) report a case in which signs of dry pneumothorax were followed 12 hours later by extravasation of blood. The second of the three examples observed by Hartzell (1942) was a youth of 17 years of age who developed a dry spontaneous pneumothorax. He was discharged from hospital with x-ray evidence of full lung re-expansion, but was readmitted nine months later on account of a spontaneous haemopneumothorax on the same side.

While the occurrence of spontaneous pneumothorax with subsequent tearing of an adhesion may be an adequate account of the course of events in some examples, a difficulty still presents itself in the understanding of why considering the very common incidence of pleural adhesions and the not infrequent pneumothorax whether spontaneous or induced, haemothorax is not more common. The resultant of the opposing forces of the intrapleural pressure and the elasticity or toughness of the adhesion will determine the issue. Should the former influence be ascendant, severance of the adhesion will ensure the degree of haemorrhage varying with the vascularity of the adhesion and the haemostatic effects of the contracting tissues and intra pleural pressure.

Almeida (1943) considers that spontaneous haemopneumothorax and spontaneous haemothorax are in all respects identical. This conclusion merits further attention. The absence of air has been attributed to the lapse of time before adequate investigation, but the interval may not be of sufficient duration to allow of complete absorption of the air, nor has the rate of absorption been studied under these circumstances. Later and Rodis (1933) published the x-ray films of a case of spontaneous haemopneumothorax in which the pneumothorax was demonstrable only with the patient lying on the sound side. The amount of air need not be great, for if enclosed in a small confined space it may exert a high pressure and so produce rupture of an adhesion with subsequent bleeding. As a tentative alternative explanation of the absence of pneumothorax in haemothorax we suggest the possibility of spontaneous rupture of an adhesion. Adhesions vary greatly in their calibre and a sudden muscular movement may rupture one of very small diameter. Should the rupture take place close to the parietal pleura bleeding will result, but no air will enter the space provided the layer overlying the lung remains intact, if the break in continuity occurs in a portion containing lung tissue then both air and blood will accumulate. Post-mortem examinations in most instances fail to reveal the source of bleeding, and it is not possible to determine whether the bleeding is parietal or pulmonary in origin. We put forward the view that the haemorrhage may originate either from spontaneous rupture of an adhesion or as a sequel to a pneumothorax. The bleeding secondary to a pneumothorax may come from the vessels in the ruptured vesicle or from an adhesion torn by the pressure of the intrapleural air. If such a contention prove valid then a distinction must be drawn between spontaneous haemothorax and spontaneous haemopneumothorax.

The cardinal symptoms of idiopathic haemothorax or haemopneumothorax are pain and breathlessness. Usually the patient previously has been in good health. The pain may be preceded by some exertion altering the intrapleural pressure, such as yawning, coughing, sneezing, or straining or it may occur while the individual is at rest. Of particular importance in some instances is the location of the pain in the abdomen, and this has led on several occasions to the erroneous diagnosis of an acute abdominal emergency, especially when other symptoms of gastro-intestinal upset—nausea, vomiting and diarrhoea—are present. The somewhat varied order of the appearance and

progress of the pain and dyspnoea may theoretically be accounted for by a consideration of the possible sequences of events which may ensue. Should a spontaneous pneumothorax be the initial incident, acute pain will be experienced. Depending on the amount of air liberated into the pleural cavity, the degree of pulmonary collapse, and the rapidity with which these processes occur, dyspnoea may appear simultaneously with the pain or some time later, and its severity be measured by the encroachment upon the respiratory reserve and the cardiac embarrassment occasioned by the mediastinal displacement. If bleeding from the ruptured vesicle takes place at the same time then dyspnoea will steadily increase to a fatal outcome or until the haemorrhage and the escape of air are controlled by artificial or natural means. The pneumothorax, if at first unaccompanied by haemorrhage, may be of insufficient degree to give rise to marked breathlessness, and pain may be the principal presenting symptom, then there may be a temporary improvement in the severity of the pain lasting for several hours to several days, only for a recurrence of the pain to ensue, but accompanied now by pronounced dyspnoea, signifying that this exacerbation represents the rupture of a pleural adhesion.

These three stages—pain (with or without dyspnoea, according to the size of the pneumothorax), temporary improvement, and recurrence of pain and dyspnoea with signs of internal haemorrhage—have been well marked in most of the recorded cases of spontaneous haemopneumothorax. When an adhesion ruptures spontaneously close to the parietal pleura and without any severance of the visceral pleural surface of the lung pain appears at once, with dyspnoea steadily increasing to its height depending on the rapidity of the outpouring of blood from the ruptured vessels of the adhesion. This course of events closely resembles that succeeding the rupture and simultaneous bleeding of a pleural vesicle, the distinguishing feature being the presence of air in the pleural sac on the latter occasion. A breach in the continuity of the surface of the visceral pleura during the spontaneous rupture of an adhesion will yield a syndrome indistinguishable from the haemopneumothorax of a ruptured bleeding bulla.

Examination of the peripheral blood may reveal an anaemia commensurate with the degree of internal bleeding. Fischer's (1922) case shows how severe the latter may be four and a half litres of blood being recovered from the pleural cavity.

The clinical course in most cases which survive the period of shock and sudden mediastinal displacement is that of slow and steady improvement. Jones and Gilbert (1936), in an analysis of 13 cases which eventually recovered found that the average duration of the disease was 59 days, with the shortest period 10 days and the longest 98 days. Hartzell's (1942) review of 43 cases shows a fatal termination in approximately 1 in 3 cases. Of 11 cases in which the available data were satisfactory, 5 died within 24 hours, 4 within a week and 2 at a still longer interval. Little information is available with regard to the incidence of second attacks, but the ultimate prognosis of recovery of respiratory efficiency appears to be satisfactory if adequate treatment is adopted. The patient reported by Milhorat (1937) enjoyed excellent health and freedom from all symptoms suggestive of pulmonary disease six and a half years after a spontaneous haemopneumothorax.

Summary

A case of spontaneous haemothorax is presented.

The possible mode of origin, the clinical features, and its relation to spontaneous haemopneumothorax are discussed.

Medical Memoranda

Fatal Aortic-Oesophageal Fistula from a Swallowed Piece of Bone

The following case of aortic-oesophageal fistula arising from perforation of the oesophagus and aorta by a piece of bone may be of interest owing to the rarity of the condition.

CASE HISTORY

A young Somali adult was admitted to a casualty clearing station for treatment of a small tropical ulcer. The ulcer was given local treatment; the patient had no other complaints. At about 5 p.m. on Oct. 7 he had a normal meal of meat and vegetables. At midnight he complained of nausea and a slight deep-substernal discomfort, and a short time later brought up about a cupful of blood-stained vomit. At about 5 a.m. the next day he suddenly vomited 5 oz. (140 c.cm.) of bright-red blood containing several clots, in which was found a flat piece of bone. Apart from a slight rise in pulse his general condition was good and there seemed no cause for alarm. The piece of vomited bone had the appearance of a cortical portion of some long bone. It was flat and polygonal in shape, and measured 3 cm. in its greatest length and 1.5 cm. in its greatest breadth. The edges and corners were sharp, and one of the long edges was serrated like a saw. A diagnosis of laceration of the oesophagus was made.

Treatment and Progress.—Morphine 1/3 gr. (22 mg.) was given and other first-aid measures for haemorrhage were begun. His general condition improved rapidly; but a blood count at 9 a.m., showed haemoglobin 40% (Sahli) and 1,830,000 red blood corpuscles per c.mm. No oesophagoscope was available. At 12 noon he suddenly vomited about 20 oz. (560 c.cm.) of bright-red blood; much of it was clotted. He was collapsed, with all the signs and symptoms of severe haemorrhage. First-aid shock treatment was given and an intravenous drip of 500 c.cm. of serum was started, followed by 1,000 c.cm. of glucose-saline and later 500 c.cm. of matched blood. His general condition improved somewhat. In the hope of being able to plug the oesophagus from the stomach a laparotomy was performed. The stomach was found to be full of blood clot. There was no lesion of the stomach. A stream of blood was seen pouring from the oesophageal opening. No lesion of the oesophagus could be felt digitally. Closure was performed, and the patient died.

Post-mortem Examination.—The body was that of a well-built, well-nourished male, and, apart from marked pallor of the mucous membranes and a small ulcer on the right shin, there was no evidence of external disease or injury. The pharynx showed no abnormality. On opening the oesophagus it was found to contain a large quantity of blood. On the antero-lateral wall on the left side, 9.5 cm. from the commencement of the oesophagus, there was an area 2 cm. long by 1.5 cm. broad which suggested that a cut had been made by a blunt knife. The mucosa was cut fairly cleanly over this area, but the muscle layers had a slightly shaggy appearance. On passing a probe into the centre of the cut it was found to emerge in the arch of the aorta 1 cm. below the origin of the left subclavian artery. The opening into the aorta was a small irregularly shaped hole about 1 mm. long, and had some blood clot lying at its edges. There was also a cut in the posterior wall of the oesophagus about 9 cm. from the origin of that organ. This cut area was 2 cm. long by 1 cm. broad. Again the muscle coat had been severed, but the wall was not perforated.

No other abnormality of the oesophagus was found. The remainder of the alimentary system showed no abnormality; and no pathological changes apart from the perforation of the aorta could be discovered in the heart or great vessels or any other organs.

The literature of the subject has been reviewed by Bank. R. S., *J. Amer. med. Ass.*, 1943, 122, 1011.

G. E. NEVILL,
Capt., E.A.A.M.C.; Graded Specialist in Surgery

Dr. Willard C. Rappleye, president of the Josiah Macy Jr. Foundation, New York, announces that more than five million copies of over four hundred leading medical and scientific articles have been published by the Foundation's war reprint service during the last three years for medical officers of the armed Forces of the United States and so far as possible Canada, England, New Zealand, Australia, the U.S.S.R., and China. The reprint service is now discontinued. It has been an effort to bring new and important developments in the science and practice of medicine to medical officers who were largely cut off from the sources of medical information during the war. In the choice of these articles the Foundation has had the active co-operation of the Committee on Pathology of the National Research Council and of the National Committee for Mental Hygiene.

Reviews

MOVEMENT OF EXTRAVASCULAR FLUID IN THE LUNGS

Pulmonary Edema and Inflammation. An Analysis of Processes Involved in the Formation and Removal of Pulmonary Transudates and Exudates. By Cecil K. Drinker, M.D., D.Sc. Harvard University Monograph in Medicine and Public Health. No. 7. (Pp. 106; illustrated. \$2.50 or 14s.). Massachusetts: Harvard University Press; London: Oxford University Press, 1945.

An outcome of recent work, employing isotopes, on the distribution of ions throughout the body and of estimations of the volumes of the fluid compartments of the organism by a variety of methods has been the appreciation of the rapidity with which transport and distribution of substances is effected across the various membrane barriers.

In this short monograph, which contains the substance of the Nathalie Gray Bernard lectures, Prof. Drinker deals with the movement of extravascular fluid in the lungs. He regards the formation and circulation of lymph in the lungs, and the production and removal of alveolar transudates and pleural effusions, as parts of one large problem. The factors affecting fluid exchange, while similar to those operating in other tissues, are modified by the mechanical conditions under which the lungs work. The minute anatomy of the lungs is first reviewed, and then follows a description of the experimental methods by which the lymph from the lungs can be collected. The salient differences, often disregarded, between the systemic and the pulmonary capillaries are examined particularly with reference to the pressure relationships of the blood vessels, air passages, and lung tissue. The factors which may disturb the normal balance between the rate of tissue fluid formation and lymph drainage are discussed and, by reference to his own experimental work, the influence of anoxia on capillary permeability is stressed. From observations, both clinical and experimental, it is concluded that limitation of lung movement, slight respiratory obstruction, or anoxia produced in any way, may give rise to a degree of pulmonary oedema which, while insufficient to be revealed by ordinary clinical examination, may encroach upon the pulmonary reserve, prevent the free exchange of pulmonary gases, and provide conditions suitable for the spread of infectious inflammation. In a concluding chapter present methods of artificial respiration are reviewed, not only for their effect on ventilation but also for the changes likely to be produced in the lungs by the particular method employed.

Although the problems raised are not new and the consideration given to them is necessarily rather superficial, yet the approach to them is stimulating, as may be anticipated when the way is by the author's own investigations, and the majority of them are of fundamental importance to the physician, the anaesthetist, and the thoracic surgeon.

HISTORY OF SCIENCE

Science Past and Present. By F. Sherwood Taylor, Ph.D. (Pp. 270; illustrated. 10s. 6d.) London: Heinemann, 1945.

Dr. Sherwood Taylor has had the excellent idea of putting together a history of science which is also a "source book." Each of his eighteen chapters—beginning with man's first efforts to make flints, and ending (inevitably) with the atomic bomb—is followed by a series of quotations from contemporary writers which, in their cinematographic effect, give a livelier impression of the knowledge and outlook of successive generations of inquirers than can be obtained from much more ambitious histories. His chapter on "The Revival of Observation"—the sixteenth century—provides a good illustration of the method. The main text compresses into a matter of eight pages a general sketch of the Renaissance and a sufficient survey of the science of the period to establish the point that astronomy and anatomy were the only branches in which outstanding advance was being made. Then we come to the quotations: Copernicus's explanation of how he "began to think about the mobility of the earth"; Vesalius's demonstration in a sow of "the connexion of the voice with the recurrent nerves" ("This animal is chosen because it can be relied on to squeal continuously and so provide the voice which is the subject of the experiment"); a typical prescription, from Fumanelli.

compounded of filtered lizards, marjoram, and wormwood; Edward Wright's story of "an ancient mariner (yet living I think) who having undertaken the charge of conducting a ship from England to St. Michael's (the easternmost of the Azores) and after long seeking not able to find it, for shame and sorrow cast himself overboard"; and, finally, the elaborate directions of Robert Recorde in 1542 on how to multiply "seven times eight," given that "five times five" is the limit of tables that one can be expected to know. In the same short chapter there are ten illustrations, all aptly chosen, from original sources. Primarily written for sixth-form and university students, this is a book which few can afford to despise.

A MEDICAL TRACT

Birtricht. By Tustaa Cluver (Pr 165 8s. 6d.) Johannesburg Central News Agency, Ltd. 1945.

This is a mixture of something like a fairy story with ardent propaganda for a whole time salaried medical service. The author is an enthusiastic advocate of prevention rather than cure, and like most such, his interest is in the mass rather than in the individual whose eccentricities, likes and dislikes, are of small account in comparison. It is probably fair to infer that the author is the eminent Director of the South African Institute for Medical Research, whose views are therefore worthy of respect.

The fairy-story element is provided by a running account, first of what the world was like in the days of our very remote ancestors, and then by the experiences of a "Dr. Fortescue," a general practitioner who arrives at a strong belief in the necessity for a State Medical Service and discusses the matter with his patients and his colleagues. Man's birthright is his right to be healthy, happy, and contented, and to live to a much greater age than at present seems possible. This can be achieved only by planning, and the author believes that Russia is doing this now. Dr Cluver says that, though the medical profession has its ideals, these "can never be realized until disease treatment ceases to be profitable. The profession as a whole is not making the contribution to the health of the community commensurate with its numbers; it is far too much concerned with treatment and too little with prevention." The present low average of physical health is attributed to the evils of civilization—starchy foods, too much clothing, lack of ventilation, economic insecurity; and on these points much of what the author has to say is interesting and sometimes very sound. There are many passages which the reviewer found provocative, and one at least that seemed quite out of place in a book which must have been intended to be persuasive. There is a long argument about a salaried medical service, conducted with great spirit during an operation which ends in the death of the patient owing to the mismanagement of the anaesthetist, who, of course, is arguing in favour of private practice, while the surgeon takes the other side. The jury brings in a verdict of accidental death, but it was probably not aware of the absorbing controversial activities of the two doctors concerned.

The account of his visit to Russia in 1939, and the effect it had on the doctor, is well told. It conveyed to one reader the impression of a man all too willing to be confirmed in ideals previously formed, and now, he thought, put into practice. At first the doctor was rather depressed by the drabness and shabbiness of the man and woman in the street and by the marked lack of enthusiasm shown by those concerned in running the hotel at which he stayed in Moscow. However, it was explained to him that waiters are generally chosen for the job because they have proved useless for other more useful occupations. But as soon as he got into the institutions dealing with the masses he was enchanted. He admits that he encountered much dirt and overcrowding (not in the institutions) and saw much evidence of the results of early malnourishment, but, he goes on to say, "the health plan as I saw it approaches perfection," and he shows very clearly that in many directions the Russians have made immense progress, particularly in maternity and child welfare, in industrial medicine, and in the reduction of prostitution and venereal diseases. Dealing with the medical profession, he says that in the selection of students preference is given to manual workers, which accounts for the lack of preliminary general education which he noted. Students are paid salaries and allowances during their

curriculum. When a doctor qualifies he must go where he is sent, but there is little reluctance (which anyhow would not be tolerated) about going to remote areas, because the salaries are higher there and the cost of living less. An "experienced doctor" would be paid the equivalent of £40 a month; which is deemed good pay, as it is "as much as is earned by the most skilled worker," such as the miner. Traces of the "old Adam" appear when we are told that in rare cases higher salaries can be earned, even as much as £160 a month. This is achieved by giving a doctor four *whole-time* appointments. The author comments frequently on the great disproportion between men and women doctors: the women seem to be in a great majority. Russia discourages domiciliary attendances, and the author admits that it is "quite impossible to attain to the close personal relationship implicit in private practice." But as most of the people have never experienced this they don't mind, and Dr. Cluver obviously thinks it of little consequence when it is compared with the benefits the Russian system has conferred on the mass. A non-Russian patient might have other views.

Space does not allow of reference to many other interesting points noted by an acute if biased observer. The author's idealism appears occasionally to overcome his sense of proportion. Optimism runs riot through the story. "In the not too distant future we shall have cured the last case of infectious disease of any kind." "Clinical diagnosis has become supererogatory. The drugs available are so general in their action that it is no longer necessary to label the disease which is about to develop." "The doctor of the future will have the job of keeping lots of healthy old men and women in their contentedly happy state." We can envy Dr. Cluver his optimism even if some of us are not able to share it.

Notes on Books

The Ministry of War Transport has issued from Berkeley Square House, London, W.1, two revised memoranda on *Malaria among Merchant Seamen*, which supersede earlier editions. The first and longer, officially described as Notice No M 195, gives suggestions for the prevention, diagnosis, and treatment by ship surgeons of malaria on ships. It describes general and medical precautions, clinical manifestations of malaria, diagnosis and prognosis, general management of a case, and specific treatment of an acute attack. One appendix is on the technique of parenteral administration of antimalarial drugs, and another on toxicity of mepracine and pamaquin. The second and shorter memorandum, Notice No M 178, is primarily intended for the use of masters of vessels that do not carry surgeons, and the instructions are confined to such measures of prevention and treatment as can be carried out by the layman.

The Junior Club Handbook: a Guide to the Organization of Clubs for the Under 14's is published at 3s. 6d. by the Religious Education Press, Wallington. During the war, owing to the absence of parents on war work and the temporary decay of scout and guide activities due to lack of leaders, the leisure of school-children was poorly provided for and organized. Probably this was one of the major causes for the increase in juvenile delinquency in recent years. Attempts have been made to form clubs for these school-children by many well-intentioned individuals and organizations, but they have been by no means uniformly successful. In 1943 a committee was formed and made a survey of three representative boroughs, and was dissatisfied with what it found. Learning from the mistakes it discovered, the majority of its members have contributed articles dealing with their respective spheres of interest to make up the present guide to the formation of junior clubs. Play, the use of the arts, outdoor activities, and religion are discussed seriatim in the first part, and details of games, dancing, and handicrafts are supplied in the second. A useful bibliography and list of addresses is appended, but it is regrettable to find no mention of child guidance, which has an important contribution to make towards the understanding and upbringing of normal as well as abnormal children. On the whole this little book provides useful suggestions for all who take a practical interest in our citizens of the future.

Dr. MARIE-LOUISE VERRIER'S *Biologie de la Vision* (Paris: Librairie Armand Colin; 42 francs) is essentially an account of the comparative physiology of the eye. It also gives a considerable amount of incidental comparative anatomy. As a concise elementary exposition it leaves little to be desired. The excessive stress on French work is rather unfortunate.

SATURDAY JANUARY 19 1946

SPRUE

It is not unusual for anthropologists to lament that so little information was gathered about the structure and customs of primitive communities when the white races first penetrated into Africa and the Pacific. We must sometimes wonder, therefore, whether scientists of the future may not look back on the war-stricken decades of the first half of the twentieth century as the golden opportunity for nutritional research. The answer is almost certainly No. The poorly nourished are likely to be with us for many years to come, and, though war subjects mankind to strange and testing circumstances, it does so under conditions which are not devised for dispassionate observation or control. In this war the experiment has been made of sending huge armies of men with the latest equipment of technology into India, South-East Asia, and the Pacific. The scope of the attack was without parallel in the history of warfare, and its success was largely due to applied science. The amount of new knowledge gained in the field has nevertheless been relatively small, owing to the basic difficulty under which both military medicine and tropical medicine labour—that is, to bring together the clinical material and the facilities for investigation, and to reconcile the urgent tempo of war with the measured pace of research. Moreover, while war accelerates the application of science, it probably retards the development of fundamental knowledge.

One of the problems of military medicine in India has been sprue, of which Keele and Bound give an account in the opening pages of this week's *Journal*. It is important not so much for the total number of cases as because of the long duration of invalidity and the obscurity of the pathology. The interest of these war cases is that the patients have been seen at a stage before the development of anaemia and complications. They have, in fact, been seen so early that they raise the question as to the essential features on which a diagnosis of sprue should be based. Keele and Bound found that isolated samples of stools from their patients might contain a normal percentage of fat; but analysis of single specimens is of little value, as Frazer and his colleagues pointed out at a recent meeting of the Gastro-Enterological Society. The only way to determine the presence of steatorrhoea is to carry out an actual fat balance, in which the patient is given a measured intake of fat over a period of days, and the amount not absorbed is estimated by collection and analysis of all the faeces passed. We should be unwilling to abandon steatorrhoea as the cardinal symptom of sprue without the evidence of such experiments.

The designation "sprue" was given to the illness because of the *aphthae tropicae* with which the patient's mouth is sprinkled, while the synonym "psilosis" refers to the bald tongue. There can be no doubt that sore mouth and catarrhal inflammation of the entire alimentary tract formed the basis of the classical description of sprue. There are, however, other tropical diseases in which sore mouth, diarrhoea, and wasting occur, such as pellagra, kwashiorkor or malignant malnutrition, and ariboflavinosis. The distinction between sprue in the white troops and marasmus in the coloured troops in the Burma campaign is so fine that one would doubt whether it could really be drawn by clinical means. If we are to make further advances in the understanding of nutritional disease we must discover objective criteria for classification, comparable with the bacteriological and serological criteria of infectious diseases. These may be found by the isolation of aetiological factors and the recognition of specific disturbances of form and function. The tendency in recent years, therefore, has been to rely rather more on the laboratory data than on the clinical signs, and steatorrhoea has been the criterion by which sprue has been separated from similar conditions such as pellagra and nutritional macrocytic anaemia in cases of doubt. It may be that steatorrhoea will prove to have as many different origins as stomatitis and diarrhoea, and to be a phase and not a primary symptom of the illness we call sprue. Nevertheless, for the moment it would seem profitable to regard steatorrhoea as an essential element in diagnosis and research on sprue.

If sprue is so difficult to define it is not surprising that its aetiology remains a puzzle. Sprue occurs in America, Asia, and Australia, but apparently not in Africa. It sometimes appears in epidemic form, and may be so localized as to give rise to the idea of "sprue houses." It affects the more prosperous section of the community. There is a pronounced seasonal variation in incidence. All this is difficult to harmonize with the conception of a nutritional deficiency, but efforts to discover a specific infective agent have failed. In a review of the aetiology of sprue A. W. D. Leishman¹ suggests that micro-organisms may be playing a different part from that with which we are familiar in the infectious diseases. It has been known for some time that though pellagra is associated with deficiency of nicotinic acid it predominantly affects the maize-eating people of the world. It is now believed that a maize diet is unfavourable to the absorption of nicotinic acid, whereas biological proteins and tryptophane are favourable. The action in both directions is believed to be brought about by the changes in the intestinal flora which result from the different diets. In sprue Leishman suggests that a change in the intestinal flora consequent on residence in the Tropics depresses the absorption of nutritional principles which are concerned with the assimilation of fat. This is an interesting speculation, which suggests that the conception of intestinal toxæmia may be revived in a new guise, but it will be impossible to prove or disprove it until we know more about the absorption of fat. A further problem raised by these war experiences is why sprue is

on the whole curable, while the idiopathic steatorrhea seen in this country tends to persist throughout life. The conclusion we would draw is that advances in the prevention and treatment of sprue must wait on basic physiological studies. The new hypothesis of fat absorption advanced by Frazer⁷ and his colleagues promises to be very fruitful, and it may well be that the problems of sprue will be solved in the laboratories of Western Europe and the U.S.A. rather than in the countries where the disease is prevalent.

INFECTIOUS DISEASES IN THE LENT TERM

The trend of infectious diseases during the war years has shown no very marked deviations from the average, though the returns for the last two years suggest that infectious diseases in general were less prevalent than in the earlier war years. Only two diseases—diphtheria and dysentery—have undergone a notable change in incidence and their trends have been in opposite directions. The notifications of diphtheria numbered 25,059 in 1945; this was a record low level, being only half of the number recorded in the early war years. Dysentery has steadily and rapidly increased during the war, and the 16,533 notifications in 1945 were six times greater than the total for 1940. Most infectious diseases have a distinct seasonal rise, with a heightened incidence in the winter months and often with a maximum during the first quarter of the year. The most outstanding disease for its regularity of appearance and shape of the epidemic curve is influenza. The annual trend of influenza since the pandemic of 1918-19 has been to increase slowly in the late autumn, with a more rapid rise in late December or early January to a maximum in the early weeks of the year. In recent years the peak of the mortality of the great towns has varied from the fourth to the eighth week. The only exception to the customary influenza pattern occurred in the winter of 1943-4, when influenza began to rise about two months earlier than usual and the mortality in the great towns reached a maximum during the 49th week of 1943. An outbreak of influenza has usually spent its force by the end of the first quarter, but in years of unusual severity the epidemic may last well into the second quarter. During the large epidemic of 1929 the deaths in the great towns reached a maximum of 2,183 in the ninth week, but it was not until the week ending May 11 that fewer than 100 deaths were recorded weekly. The deaths from influenza in the last weeks of 1945 were above the average, but it does not necessarily follow that the present outbreak will exceed those of recent years, though it does seem a likely occurrence.

The common infectious diseases of childhood are more prevalent in the winter; but for scarlet fever, whooping-cough, and diphtheria there is no very definite maximum: the incidence oscillates around a high winter level. The notifications in the first quarter are higher than in the preceding fourth quarter for whooping-cough, while the reverse is true of diphtheria. In the first quarter of 1945 the incidence of diphtheria fell instead of remaining almost

at the level of the preceding quarter, as would have been expected from the experience of the preceding years. Any hopes that a large continuous fall in the incidence of diphtheria had been achieved were disappointed later in the year, when the figure reverted to the level of 1944. If the present trend of diphtheria goes on we must expect a considerable increase in notifications during the Lent term compared with last year, though the number of cases should be below the 9,005 recorded in the first quarter of 1944. Measles has been a notifiable disease only since the war began, and during this period it has exhibited a biennial periodicity with maxima in the first quarters of 1941, 1943, and 1945, the largest weekly totals occurring in the 1st, 8th, and 12th weeks. In the coming quarter we may expect measles to rise, and judging from the past six years the incidence will continue to rise until a maximum is reached in the spring of 1947. As in 1914 the outbreak of war, with the consequent massing of great numbers of men, was followed by a large outbreak of cerebrospinal fever. Before 1939 the incidence rose in winter to about twice the summer level, but without any definite peak. Since 1939 a rise to a pronounced maximum in the first quarter of the year has been a feature of the incidence of cerebrospinal fever, the peak incidence appearing from the 6th to 12th week. In each succeeding annual wave the number of cases has declined: the successive maxima were 617, 406, 281, 121, 101, 94. Cerebrospinal fever seems to have become temporarily stabilized at about twice the pre-war level, and the coming spring will probably show figures of the order of those of the past two years, since the autumn trends of these years are similar.

Acute pneumonia displays somewhat the same trend as the influenza mortality of the great towns. The winter rise of pneumonia starts earlier than the rise in influenza mortality, and although, generally, the number of cases recorded in the first quarter is much greater than the number in the preceding fourth quarter there is no sharp rise to a maximum in the first quarter; rather the incidence tends to remain at a high level for some weeks. The only recent exception to the general trend of pneumonia occurred in 1943-4, when the maximum was reached in the 49th week, this coincided with the maximum of the influenza outbreak, which was exceptional for time of occurrence. Since in recent weeks acute pneumonia has been at a higher level than in the corresponding period of last year the notifications in the forthcoming quarter will probably be more numerous than in the first quarter of 1945. Dysentery displays no seasonal trend, and this might be expected because of the localized area of outbreak; but the disease has shown a large and continuous rise throughout the war: 4,681 cases of dysentery were notified in the first quarter of 1945, and compared with some pre-war years the notifications have multiplied over twelve times. Of the non-notifiable infectious diseases rubella, which may sometimes in a closed community exhibit powers of spread equal to influenza, appears in the first and second quarters in epidemic form, and attack rates of over 90% among the susceptibles in the population (i.e., those not previously attacked) have been recorded. It would seem from field investigations that chicken-pox has not a well-marked seasonal rise and that it emerges

in a closed community of boys and girls more frequently than any other infectious disease, though numerically it is not the most important. The work of many epidemiologists has established that the Lent term has the largest prevalence of nasopharyngeal infections. Both in this country and in America a maximum incidence has been found at about the end of the first month of the quarter.

JUVENILE DELINQUENCY AND ITS REMEDY

The recent debate in the House of Commons shows that the problem of juvenile delinquency arouses great concern but not much constructive thought. Mr. F. W. Skinnard, M.P., who is an expert on the maladjusted child, has put the problem into perspective in an article which stands out as one of the most sensible written on this subject for a long time.¹ His chief point, and one that ought never to be forgotten when thinking about juvenile delinquency, is its fundamental difference from adult crime. If the child charged with an indictable offence is the embryo of the habitual adult offender, and if juvenile delinquency is constantly increasing, then the adult convict population should be growing. In fact, as Mr. Skinnard points out, serious adult crime is decreasing; the vast majority of adult criminals have no police record as children, and a very small percentage of children brought before the courts ever appear again. That juvenile delinquency has increased seems to be generally accepted, but the amount of its increase is largely a matter of statistical recording. After the passage of every Act concerning delinquency the recorded figures shoot up. Sir William Clarke Hall declared that the number of child offenders in any locality can at any time be multiplied merely by exceptional police activity. The principal cause of child delinquency is the failure of the community to give children something sensible to do. The child will not allow his valuable instincts and talents to rust, even if the only uses to which he can put them are illegitimate. He is not content, as grown-ups are, with repetitive work and canned amusements. The community has remained strangely passive to the vital need of providing a creative outlet for youth. Its interest is manifested mainly in administrative and permissive measures sweetened by grants in aid; there is no comprehensive plan. It is concerned with the activities of adolescents only when they break the law. Mr. Skinnard sketches from practical experience the lines which reform should follow. First, he says, all the work of the school should tend outwardly towards the community at large, so that there is a conscious integration. Secondly, the school should aim at attracting inwards the interest and active attention of the adult population. The whole curriculum should aim at turning out young citizens with a real concern for the well-being of their district. He narrates how the work of drawing up a simple social and economic survey of the locality transformed a group of young delinquents into a keen self-governing body, and also produced an amazing reaction in the world around it. Previously hostile parents gave valuable help; adult classes were formed; local firms contributed equipment and demanded intelligent "leavers" to train for executive posts. Petty crime became nearly extinct. Mr. Skinnard concludes that if the youth of the world are taken into full partnership and given tasks worthy of their courage and matched with their ability they will help to build the only true democracy, based on a unity of spirit in a diversity of minds.

ARSENIC IN TOBACCO SMOKE

In 1927 Remington¹ drew attention to the fact that tobacco smoke was an unsuspected source of arsenic in the human environment, and made some experiments which showed that about half of this arsenic was volatilized when the tobacco was smoked. Further observations were made in 1934 by Gross and Nelson,² who found that between 15% and 40% went into the smoke while the rest remained in the ash and cigarette-ends. Last year Thomas and Collier,³ of Salt Lake City, carried out smoking experiments with cigarettes, cigars, and pipe tobacco, and made determinations of the arsenic content of the puffed smoke, the unpuffed smoke, the ash, and the cigarette- and cigar-ends; they controlled the experiment both by estimating the arsenic content of small portions of the cigarette smoke and by analysis of whole cigarettes from the same packet. These observations revealed that different brands of tobacco and also individual cigarettes and cigars of a given brand varied widely in arsenic content: one packet, for instance, gave values ranging from 35.4 to 61.4 parts per million of arsenious oxide, while another gave values between 61.4 and 114.0 p.p.m. The smoke from these cigarettes contained between 11% and 23% of the arsenic, while the rest was distributed between the ash and the ends. The concentration of arsenious oxide per cubic metre of the puffed smoke ranged from 0.2 to 3.0 mg. for cigars (which, however, contained less arsenic than the cigarettes or smoking tobacco), 1.7 to 5.7 mg. for pipe tobacco, and 3.3 to 10.5 mg. for cigarettes.

These observations are of interest because of their possible relation to carcinoma of the lung. Last year the Chief Inspector of Factories⁴ stated in his annual report that three similar cases of pulmonary carcinoma occurring in arsenical sheep-dip workers had been notified since 1939. He also drew attention to the high incidence of carcinoma of the lung in arsenic workers, and stated that in conjunction with the Medical Research Council investigations were being carried out on this problem. Although the matter is not finally settled, there is strong evidence that exposure to arsenic dust predisposes to carcinoma of the respiratory tract. Much attention has been paid to the carcinoma of lung which occurs in miners in the Schneeberg mines in Czechoslovakia. The dust produced in the drilling of the hard rock is radio-active, and the neoplastic change has been generally attributed to this; the dust, however, also contains 0.45% of arsenic, which may play some part in the aetiology of the disease. The nickel and copper ores from the Sudbury mines in Canada also contain arsenic which may account for the carcinoma which sometimes develops in the upper respiratory tract of workers who handle this material.

Most observers agree that there has been a general increase in the incidence of carcinoma of the lung during the past two decades, though it has been suggested that the increase is not real but the result largely of more accurate diagnosis and a longer-lived population. During the same period there has been an enormous increase in the consumption of tobacco. Now that tobacco smoke is known to contain a substance having carcinogenic properties when introduced into the respiratory tract, the question immediately arises whether the two increases are in any way related. There is at least a case for full investigation.

JITTERY LEGS

Pain, aching, discomfort, or dysaesthesiae of a burning, tingling, "pins and needles" character are all symptoms which may affect the feet and legs with such severity or persistence as to drive the victim to seek medical advice. In such circumstances differential diagnosis may be difficult, especially if there is a lack of objective abnormality on examination. Largely by exclusion, the search narrows to a scrutiny of the peripheral nerves, the crural blood vessels, and the muscles, with such possibilities in mind as sensory neuritis, an early thrombo-angitis, or a non-articular rheumatism. But as a rule a wholly satisfactory explanation of the symptoms does not emerge. K. A. Ekblom¹ has described recently a syndrome which corresponds with the more vague and elusive of these clinical phenomena. The complete picture, as he draws it, comprises peculiar and characteristic paraesthesiae in the lower legs, especially at night; weakness or clumsiness of the legs while walking, and a sensation of cold in the legs or feet. Objective signs are not to be found. Ekblom regards this disorder as "unpleasant, of long duration, and rather common." At the time of writing his paper the author had studied 8 cases, but by the time of correcting the proof-sheets the series had grown to 30. By the following year his material comprised 34 severe and 120 mild cases, and was incorporated within a short monograph.²

The symptoms may be examined in greater detail. The paraesthesiae ("dysaesthesiae" is a better term) are not easy for the patient to describe accurately. They are located deep in the leg, in the calf or shin; rarely in the feet; occasionally in the thighs. It is a crawling sensation, "irritating and enervating." All agree that it is something very unpleasant. Although often described in terms of "nervousness" the victims disclaim any association with feelings of an anxiety. The dysaesthesiae mostly come on at night, an hour or so after getting into bed. They prevent sleep. Since the sensations are relieved by moving the legs, the patient is compelled continually to change his position, and to kick, turn, and fidget in bed, or even to dangle the legs over the edge. Some indeed have to walk about the house. The dysaesthesiae may continue until the early hours of the morning. Two of Ekblom's patients used to pass the night reading or sewing. This state of affairs may continue night after night for years, even decades. During the day the legs are usually comfortable, though sometimes the dysaesthesiae will appear towards the evening when the legs are still—as in the cinema. The weakness of the legs is a less constant feature, and it consists of a vague feeling of heaviness or tiredness, especially after a long walk. It may cause the patient to stumble; it may seem as though the legs were going to give way; in one of the author's series they actually did crumple up on many occasions. Coldness of the feet and legs is the third symptom, though not always present. No constant abnormal signs can be demonstrated. Weakness and ataxia are absent, and reflexes and sensation are normal. Objective coldness of the legs, or discoloration, cannot be found. Pulsation in the dorsalis pedis arteries is normal. Oscillometric examination was done in one case and proved normal. The blood pressure was raised in some, but not in all. One woman had varicose veins in her legs. The Wassermann reaction was negative in all cases in which this test was done. A familial occurrence is not rare. Severe cases were commoner in females, and there was an association in some cases with pregnancy.

A search of the literature brought to light a condition described in 1861 by T. Wittmaack³ under the term "anxietas tibiærum"—"a singular but an appropriate name,

for it is really as though a restless spirit had flown into the legs of the patients. They change the position of the limbs every moment." R. Bing⁴ also mentioned this affection in 1913—"a dull feeling, difficult to define, in the shin bones" . . . "my legs become panic-stricken." F. G. Allison⁵ has recently written of a condition he called "leg jitters" which reads very like Ekblom's syndrome.

For the complete syndrome (anxietas tibiærum, weakness, and coldness of the legs) Ekblom suggested the term "asthenia crurum paraesthetica," or "irritable legs." Later he preferred the term "restless legs." In his later paper he also described a painful variety he called "asthenia crurum dolorosa." This picture is less clear-cut and less commonly encountered. He draws an analogy between the paraesthetic variety and the so-called acroparaesthesia of the hands so common in middle-aged women, but nevertheless believes that the two are distinct. He also refers, in discussing differential diagnosis, to the *acromélgie nocturne* of J. Tinsell⁶ (syn. *causalgia nocturna spontanea des vieillards*); or *pseudo-erythromelalgia* of W. Craig and B. Horton⁷. Here there is a burning sensation in the feet which occurs at night and which causes the patient—usually an elderly man—to toss and turn, or expose the feet to the cold night air, or to tramp the bedroom. This syndrome, too, is a thing apart. It is suggested by the author that the condition of "restless legs" is due to a functional disorder of the peripheral circulation, but it is not clear what he has in mind in his use of the term "functional."

In 23 out of the 29 cases rapid and striking improvement followed the use of benzylhydrazoline hydrochloride in the dosage of one tablet of 0.025 g by mouth thrice daily; or the oral administration of carbaminoylcholine chloride—4 tablets of 0.002 g a day. One case responded to injections of acetylcholine. Allison found benefit from chewing a tabella of nitroglycerin gr 1/100 (0.65 mg).

It is probable that this condition is by no means uncommon but that it rarely reaches the attention of a medical practitioner and scarcely ever receives a mention in the literature. Its close association with disturbed sleep raises the question as to which is causal—i.e., whether an organic vasomotor affection of the legs interferes with sleep, or whether, on the other hand, a condition of psychogenic insomnia brings in its train various symptoms as somatic expressions of tension, irritability, anxiety, or fatigue. The association with states of anxiety and overwork certainly needs closer scrutiny. From a mere physical approach there is some suggestive evidence of an association with states of recurrent fibrositis on the one hand, and with migraine on the other. As regards treatment, it is noteworthy that sedatives of the barbiturate class are helpful, while even more efficacious is the nocturnal administration of aspirin gr 10–15 (0.65–1 g). Relief is also obtained from the wearing of heavy wool night-stockings.

The Air Ministry announces that Air Vice-Marshal A. Grant has been appointed Director-General of R.A.F. Medical Services from March 1, in succession to Air Marshal Sir Harold Whittingham, who relinquishes the post on Feb 28.

WITH THE PARTISANS IN ALBANIA

BY

Major J. G. DUMOULIN, R.A.M.C.

Albania, small and most backward country in Europe, is now free of Fascist tyranny. Sixty per cent. of its 1,250,000 inhabitants live in feudal communities in mountainous areas capable of independent existence when isolated in winter months. Doctors are few, and folk-lore handed down from father to son is the chief guide to medical treatment.

Cupping was the most popular general treatment of all ills. Sometimes this was combined with bleeding, when many small incisions were made over the area before the cups were applied; a sick person with as many as twenty red or bronze circular patches on back and chest was a common sight. Racki, a distillate of fermented grapes possessed by every household, was poured on sores, rubbed into the skin, or drunk as a cure for sick man and beast. One of the more insanitary but popular forms of treatment, more especially for chest conditions, was to apply to the body in the form of a jacket the warm skin of a newly killed goat or sheep on top of which were worn four or five layers of clothing. The sick man would be so left for several weeks. It was pitiful to see whitlows three weeks old, which had received no treatment except the daily application of wet leek leaves. An original idea was provided by a keen guerilla fighter whose friend received a through-and-through wound of the chest. He found his "pull-through" with a piece of "four-by-two" handy, if unorthodox, for use for first-aid treatment. The practices of heating stones and hanging them round the neck in a bag, of incising the lower lip for diphtheria, and even of charming away pains are just examples of the backwardness of these people of the mountains.

The Italians during their four years of occupation built some modern hospitals in the bigger towns, which had good equipment if they escaped from the ruthless pillaging and destruction carried out by the Germans as they left the country. During recent years most of the 150 doctors in the country had lived in the towns occupied by German garrisons. These men were Albanians and Italians who received their medical training in Italy, France, or Greece: while some were learned, many were not well versed in modern forms of treatment. Their methods include the popular view that injections have a greater curative power than pills, while cardiotonics, haemostatics, and calcium gluconate loom high in their list of essential drugs. Italian nuns, who as trained sisters staff the largest hospitals, have done excellent work.

Common Diseases

Of the prevalent diseases, malaria, rife in the coastal regions, is the commonest. Here an Albanian without an enlarged spleen is the exception. All three forms are found, and often a mixture of parasites is present in the blood of infected persons. The Rockefeller Institute made a determined effort to control the disease, and the Italians also tried, but the war stopped their activities, so that it has become more widespread of recent years. The incidence of typhoid and tuberculosis indicates the need for organizing a public health service and improving the low nutritional standard, for these two diseases claim a high toll of the population yearly. Syphilis, commonly of the congenital type, is prevalent, and massive untreated gummas are to be seen. Neurosyphilis is rare, probably owing to the coexistence of malaria. Louse-borne typhus is endemic, the odd case being found in most towns. Outbreaks have occurred recently with a low mortality rate—in one town a single death out of eighty cases—but there is always the possibility of a massive epidemic in a louse-ridden population. The doctors, well aware of this, are organizing disinfection centres in the larger towns.

In the winter of 1943-4 frostbite among the guerilla fighters was not uncommon, our worst case requiring bilateral amputation just below the knee-joint, for which a carpenter's saw well soaked in disinfectant had to be used. Of great interest to me was the apparent high resistance and courage of these men: for example, we had no deaths in ten patients with compound fracture of the femur, who probably had been carried on an improvised stretcher for several days or with stinking suppurating wounds reached the surgical centre riding on a mule. This, in view of the general malnutrition, is amazing: practically no vitamin C is taken in the winter diet of the mountain villager, and yet clinical nutritional deficiency appears to be rare. Of the diseases associated with the Tropics, bacillary dysentery is seen in the summer, but amoebic dysentery is uncommon. Cases of trachoma and kala-azar are evident.

War has stopped the activities of what public health services there were functioning in the towns. Tirana, the capital, alone had a good midwifery service, but in the smaller towns an ambulance and nurses' training service used to exist under the guidance of the local Red Cross.

Achievements of British Doctors

Mention may be made of the type and scope of work I undertook. There is no doubt that some valuable work has been done by British doctors working in the enemy-occupied countries of the Balkans, and their limited efforts have been much appreciated. Their job has consisted in assisting the guerilla forces to establish a form of medical service in the mountains, forming first-aid and hospital units, giving advice as well as doing the surgery and ordering medical stores.

But many factors limited the scope of these activities. It was essential to run only small units which could be packed up and loaded on mules at an hour's notice, for mobility was very important. In the early days there was no evacuation, so that to establish lines of evacuation meant the herding together of casualties in a centre too big to move and probably the goal of a German drive, which invariably took the form of an encircling movement. At such times, when fighting would be at its heaviest, little more could be done than glorified first aid; then we would split up into small parties and lie low until the Germans returned to the more congenial life in the towns. Having managed to hide the bulk of our equipment, we would then start to collect and treat the now grossly purulent wounds which had been sustained a week or more earlier. Under such conditions it was usually impossible to operate on urgent head, chest, and abdominal wounds, and it was surprising to have two patients with abdominal through-and-through injuries make a complete recovery in a few days; they would most certainly have undergone laparotomy had conditions been more favourable.

The tremendous benefit which followed the making of landing strips for aircraft and the running-in of ships to small coastal bays under cover of darkness changed the whole outlook for the wounded and raised the morale of the partisans more than any other factor; and credit must be given to the bravery of those concerned in carrying out these hazardous operations. At no small cost the Albanians have driven the Fascist occupiers from their country. Now they look to the great task of rebuilding their impoverished country. Like so many countries in Europe to-day, Albania is undergoing the after-pains of liberation, but there are people who have the foresight and knowledge upon which to build a sound health service in a country that has been backward for so long.

THE INVESTIGATION OF NUTRITION
ATTEMPT TO STANDARDIZE METHODS

A year ago the English Group of the Nutrition Society set up an advisory committee for the co-ordination of dietary surveys in liberated territories. It was felt that the presence in this country of scientists from many lands at a time when interest in nutrition was aroused offered an opportunity for standardizing methods of investigation.

Accordingly it was decided to form three panels to draw up reports respectively on laboratory methods, clinical methods, and methods of survey of food consumption. The Laboratory Panel had Prof. L. Fridericia, of the University of Copenhagen, as its chairman; the Clinical Panel, Dr. H. M. Sinclair, of the Oxford Nutrition Survey; and the Surveys Panel, Dr. E. Bransby, of the Ministry of Health. The members were drawn from the League of Nations Health Organization, U.N.R.R.A., the Army Medical Directorate, the British Paediatric Association, and other bodies, and included experts from the United States and other countries. Prof. J. R. Marrack, director of the Bureau of Nutrition Surveys, was a member of all three panels, and evidently did much of the co-ordinating work.

The reports of two of the panels are now available; special difficulties have arisen in connexion with the report of the Clinical Methods Panel, which will appear later.* The two reports already available—one dealing with laboratory methods, and the other with dietary survey technique—must be the most comprehensive ever prepared in their respective fields.

Diversity of Laboratory Standards

The object of the Laboratory Panel is to ensure that the results of laboratory examinations on the state of health and nutrition of different groups of people, or of the same groups at different times, are expressed in figures which have the same meaning throughout the world. Unfortunately, owing to the difference in methods used, in the assumptions on which calcu-

* Copies of the reports will be supplied to persons undertaking surveys of nutrition, on application to the Nutrition Society, Bureau of Nutrition Surveys (Prof. J. R. Marrack, Director), London Hospital, E.1.

lations are based, in the standards adopted, and in personal factors, and to errors in instruments and different ways of expressing results, this uniformity is far from being obtained. An example is given of estimations of haemoglobin, which may be based on a variety of chemical and physical properties of haemoglobin itself and its derivatives. Results may be expressed in terms of oxygen capacity, iron content, weight of haemoglobin (and in calculating the weight the factors used may differ), or percentage of a conventional normal, and the conventional normal may range from 118 to 172 g. per 100 ml. The panel has therefore made a number of recommendations with a view to securing rapidity and simplicity in the methods used in surveys, standardization of apparatus, and expression of results in absolute units.

After some general recommendations concerning the proper taking of samples of blood the report enters upon a technical discussion of the estimation of haemoglobin. When a colorimeter of the photo-electric, photometric or Duboscq type can be used the alkaline-haematin or the pyridine-haemochromogen method is recommended; when the colorimeter cannot be used then methods based on the estimation of the specific gravity of whole blood—namely, the copper sulphate method or the Linderstrom-Lang gradient—may be applied, or, if simpler types of colorimeter be used, the Sica or Haldane methods may serve. All methods should be based on ultimate standardization against the oxygen capacity of normal blood estimated by van Slyke's method, or the iron content of haemoglobin or of washed red cells of normal blood, or the absorption spectrum of the haemoglobin determined spectro-photometrically. If the Haldane, Sica, or similar methods in current use are employed the apparatus should be standardized against oxygen capacity, iron content, or absorption spectrum, but if such standardization is not possible, an approximate, indirect standardization may be obtained by the alkaline-haematin or pyridine-chromogen method, or, if this also is impossible a rough check can be made by the copper-sulphate method or Linderstrom-Lang gradient.

It is also urged that all results should be expressed in terms of grammes of haemoglobin per 100 ml. of blood. It is recognized that many investigators will continue to use the methods with which they are familiar and those for which they have apparatus, and that some surveys in which such methods are used have already begun. The Sica method of using reduced haemoglobin is specially recommended because it does not involve the accurate measurement of a small volume of blood. The Haldane method, again, has the advantage that the necessary apparatus, standardized by the National Physical Laboratory, can be obtained.

Haemoglobin Concentrations

The report includes a table giving the results of a large number of investigations of haemoglobin concentration by different workers in all parts of the world during the last twenty-five years. Among selected groups of men (students and others), all the 70 means, with 9 exceptions (3 below and 6 above), are found to lie between 14.70 and 16.25 g. of haemoglobin per 100 ml., and among the selected groups of women all the 50 means, with 8 exceptions (4 below and 4 above), lie between 12.9 and 14.15. In the unselected groups—wider sections of the population—the mean values are, on the whole, lower. Attention is drawn to observations which show that, when trustworthy methods are used, the haemoglobin level is not lower in England than in other parts of the world. The results of the British studies on children are remarkably consistent. There is evidence of a reduction during the period of the war when the food supply was least satisfactory. A large number of investigations have been made on the changes in the concentrations of haemoglobin in the blood in pregnancy, but the methods used in most of these have not been standardized.

It is pointed out that a low concentration of haemoglobin gives no indication of the cause or appropriate treatment of the anaemia. More can be learned if the erythrocytes also are counted or the cell volume measured, or both. Measurements of cell volume, although relatively few have been made, are the simplest and most trustworthy. Certain methods are also recommended for estimations of proteins in plasma or serum. These include exact and less exact estimations, and, if a dif-

ferential estimation is not needed, specific gravity methods, which are extremely quick and convenient. The urinary saturation test for vitamin-C status and the relation between its results and the ascorbic acid in the diet and in plasma is described. Elaborate equipment and special chemicals are required for the biochemical evaluation of the nutritional status of the B vitamins, so that these procedures are not easily applicable for workers in the field.

The report is brought to an end with a bibliography of about 300 references. Altogether this report, though designed to meet a passing situation, is a piece of authoritative and co-ordinated work worthy of permanent covers.

Technique of Dietary Surveys

The Dietary Surveys Panel set itself to put forward methods whereby a quick appraisal of the food situation may be made. Some of the methods recommended, such as the log-book family survey, are of general applicability, but other questionnaire methods are suitable only for the specific conditions for which they were designed. Some might suppose that ration allowances give a sufficient indication of food conditions in a community, but it is necessary to bear in mind that foods rationed in one country may not be rationed in another, that rations on paper are not always available or equally distributed, and that the "black market" cuts right across any such simple method of assessment. The extent to which black-market transactions exist will be the measure of the extent to which the nutritional situation is worsened, at least as concerns the poorer urban families. Dietary surveys under the abnormal conditions prevailing on the Continent are, of course, difficult to organize, but the more abnormal the conditions the greater the need for the surveys.

The report mentions three classes of persons concerning whom information should be obtained. (1) the "vulnerable" with special nutritional needs (infants, pre-school and school children, and nursing and expectant mothers); (2) special classes of workers essential for the reconstruction of their locality or country; and (3) any grade or category known to be badly off. The panel proposes that four different types of dietary survey be made by families, by individuals, by particular foodstuffs consumed, and by consumption in institutions and works canteens. Two family investigation techniques are suggested—one very simple and suitable for unsettled conditions and the other more elaborate, for use when conditions become more or less stabilized. The selection of samples of the population, rural and urban, the proper size of a representative sample and the presentation of results are discussed. The presentation of results comes under two heads—the actual per capita consumption of various foods—and the percentage which the nutrient intakes represent of the requirements.

The collection and analysis of such information is for the assistance of the national authorities and those responsible for the distribution of relief, so that they may have a reliable indication of the food conditions within the locality surveyed. Women students of dietetics or social workers are said to be better investigators than men, but the work also calls for the co-operation of the families investigated. The selected housewives are asked to make immediate entries on record forms of each parcel of food which comes into the house; the measurements of the food must be accurate, to the nearest gramme or decalitre, and the number and type of meals eaten out of the house by each member of the family must be set down. Again, the housewife, whilst co-operative, must not be unduly survey-conscious, or the result may be biased. It is a great deal to expect of the harassed working woman, but some of the heroines who have survived the shopping queue and the meagre larder will rise to this occasion.

Situation in European Countries

A valuable addendum to this report is a series of tables showing the nutrient values which should be applied to the indigenous European food supplies and also to the types of relief food likely to be imported. They have been prepared by a working party of experts, of which Sir Jack Drummond was one. The inquiry has covered 16 European countries. The tables give the values in calories and in proteins, fats, and carbohydrates for 70 different food commodities, with com-

ments on the position in different European countries. In Belgium, Czechoslovakia, and also in Holland for priority classes, milk is now standardized to 2.5% fat content; in Denmark the average fat content is 3.8%. In many European countries such beef as is available comes from very lean dairy cows and has about the same food value as horse-flesh. The group found that most of the wheat flour consumed in each country is around 85% extraction—in Belgium it is 90%, and in France 95%—and that to apply this rate to all the supplies for each country would involve no serious error. Considerable study has been given to the values for potatoes, and a somewhat higher value in carbohydrates (14.6 per 100 g. of food as purchased) has been adopted than the starch figure in the Medical Research Council's report. Under wartime conditions cereals and potatoes should provide more than 50% of the calories of the diet, but a diet with more than 60% of calories in this form is unattractive to the urban worker. The total fat in the diet, including the "invisible" fat of meat, milk, cheese, and other foods, should provide 20% of the total calories. A diet containing less than 10% of "visible" fat—butter, margarine, lard, and oils—again tends to be unattractive by Western European standards. Not less than 10% of the total calories should be in sugar in the case of populations accustomed to considerable amounts of it. The proportion of total calories derived from meat, fish, and dairy produce should be not less than 12%.

The investigators add that in making the appraisal of the nutritional position as reflected by the food supply information for each country, it is assumed that distribution will be based on priority provision for expectant and nursing mothers and for children, and on an equitable distribution of the balance of foods among the other groups of the population. Any other assumption makes it difficult to reach an appraisal.

The immense work represented in these reports is worthy of all commendation and is a testimony to the standard to which the science of nutrition has been raised, largely as a result of war experience. But the study of scientific minimums, while right and necessary, must never be allowed to obscure the supreme need, which is to get food, surplus to requirements if possible, to hungry populations with all speed.

THE CAMPAIGN AGAINST CANCER

The annual general meeting of the British Empire Cancer Campaign was held on Dec. 19 under the chairmanship of Lord Hailsham. The Duke of Gloucester, president of the Campaign, sent a message from Canberra testifying to his continued interest. He also paid a tribute, as did Lord Hailsham and others, to the services of Capt. E. J. C. Chapman, who has been general secretary since the start of the Campaign in 1924, and is retiring. Two informal conferences had been held, under the chairmanship of Lord Horder, at which the Royal Society and other bodies were represented, to discuss the application of recent knowledge in the field of atomic energy to the treatment of cancer. Representatives of the Campaign, as well as others who attended the conferences, had been appointed to the research committee set up by the Government on the medical and biological application of nuclear physics.

In moving the adoption of the annual report Dr. Malcolm Donaldson said that one unfounded criticism of the Campaign was that it took no notice of suggestions from non-medical people. The chance of getting any help from those who had no knowledge of the subject was small, but in fact the Campaign had an information committee which considered every suggestion submitted. Another criticism was that the Campaign did not sufficiently concentrate its efforts. Before any concentration was possible an immense amount of individual work had to be done, but through the Clinical Cancer Research Committee the time was approaching when it would be possible to concentrate their efforts, and one of the first targets might well be the problem of alleviation of pain in the later stages of the disease.

Reports from Many Centres

The annual report is a collection of records of work from cancer research laboratories in all parts of the kingdom, individual research workers, and branches of the Campaign in the

Dominions. The Middlesex Hospital Research Laboratories describe the endeavour to complete the synthesis of compounds in the stilboestrol series, but no substance of greater activity than stilboestrol itself has yet been found. Intensive research is being carried out on the metabolism of synthetic oestrogens, especially in relation to treatment of carcinoma of the prostate and of the breast. So far the application to inoperable carcinoma of the breast has led to no conclusive results. Some experiments on mice are reported from the Cancer Research Department of the London Hospital, from which it appears that the purine compounds adenylic and guanylic acid exert an inhibitory action on tumour growth; but here again further observations over a large number of mice are required before conclusions can be drawn on the specific action of the individual nucleotides on the growth of sarcomas.

A study of the pathology of operation specimens of cancer of the colon, made at St. Mark's Hospital, has shown that in that region of the bowel growths of a low order of malignancy are commoner than in other regions. The histology of the primary tumour, the extent of venous spread, and the incidence of lymphatic metastases, all point to the conclusion that cancer of the colon must be regarded as a relatively favourable field for surgical treatment, though the prospects of surgery, as in any form of cancer, depend also upon several other factors. A survey at the same hospital of cancer of the recto-sigmoid region has shown that about half the patients who survived a combined excision of the rectum were alive after five years. Those who have the best prospect of survival are patients in whom there is no local spread beyond the rectal muscle, no detectable venous spread, and no lymphatic metastases; the five-year survival rate for such cases is 82%.

Reports of work from the Royal Cancer Hospital show that a very high incidence of cancer may not be accompanied by any decrease in the incubation period. Thus the mean age at death from cancer of the scrotum is at present almost the same in chimney sweeps as in the general population (about 59 years), although the liability to the disease among sweeps is enormously greater (543 as against 4.1 deaths per million per annum). Similarly, in the case of occupational cancer of the lung, the high incidence among chromate workers in Germany was not found to be accompanied by any lowering of the mean age (60 years) at death from this form of cancer in the general population.

Radiological Investigations

At the Cambridge University Research Centre of the Campaign some detailed cytological studies have been made, by means of serial biopsies, of the effect of x and gamma rays on human malignant tumours. In carcinoma of the cervix anaplastic growths most often fail to respond to irradiation techniques. These tumours contain cells which do not differentiate as a result of the radiation given, survive exposures to heavy doses, and subsequently divide, causing a recrudescence of the tumour. Modified irradiation techniques are being investigated at Mount Vernon. One new method of application is in intracavity radium treatment of the cervix. A radium source of 70 mg. is used in the body of the uterus and two sources of 140 mg. each in the vagina; massive platinum screening makes possible a threefold increase in the minimum γ -ray dose delivered to tumour tissue.

A study of the treatment of uterine cancer by radium has been continued at the Marie Curie Hospital. Of 1,410 cases of cancer of the uterine cervix treated over five years ago, 36.9% were found to be alive. Excluding deaths due to intercurrent diseases and cases not traced, the net five-year survival rate was 38%. Radium alone appears to remain the method of choice until a combined radium and x-ray technique can be found which will deliver an adequate radiation to the tumour without increasing intestinal morbidity.

Carcinogenic Agents

Much work in many quarters is being continued on carcinogenic agents, in particular benzpyrene. One finding, from the Mount Vernon laboratories, is that a significantly greater number of tumours arise in the skin of mice pre-painted with croton oil and painted once with benzpyrene when the painting is done at midnight than when it is done at midday. The correlation with diurnal variations in mitotic activity points to the conclu-

sion that the specific action of the benzpyrene is upon the dividing cells. At Newcastle-upon-Tyne, in the cancer research laboratory of the Royal Victoria Infirmary, an extensive study has been made of the relationship between the solvent used for the injection of benzpyrene solutions into mice, the rate of excretion of this hydrocarbon, and the incidence of cancer resulting. The anticancer effect of mouse fat and brain lipids as solvents has been traced to their phosphatid content. Removal of phosphatides removes the anticancer activity. At Leeds confirmation has been obtained of a claim made in the United States that urethane, repeatedly administered, causes pulmonary tumours in mice.

Cancer of Pharynx and Larynx

The Clinical Cancer Research Committee, under the chairmanship of Lord Horder, presents each year a detailed statistical analysis of a large number of cases of cancer in a particular region. The information is obtained with the co-operation of London hospitals. This year about 500 cases of cancer of the pharynx and larynx have been analysed from every point of view—age distribution, occupation, first symptoms, type of growth, methods of treatment, five-year results, and other angles. Males predominated over females in a ratio of ten or more to one, except in the case of the oropharynx, where the numbers were nearly equal, and in the posterioroid region with a ratio of three females to one male. Only 19 of the 384 pharynx cases survived five years. Of 124 larynx cases, 26 survived for that time. Laryngofissure in the early cases gave a survival rate of 91% of the normal expectation of life over a five-year period. One part of the investigation concerned the effect of tobacco and alcohol, but the large proportion of cancer subjects concerning whom there was no information on these points prevent any conclusions from being drawn. Of 307 male patients, 232 were said to smoke in moderation, 64 to excess, and 11 were non-smokers, and of 291 whose history in respect of alcohol was known, 227 took it in moderation, 27 to excess, and 37 were total abstainers.

One industrial precaution mentioned in the report by investigators from the Middlesex Hospital Research Laboratories concerns persons exposed to risk in luminous-dial factories. An account of the measurement of radon contained in the air of many such factories is given. It is inevitable that the air in such factories should contain some radon, but it can be kept down to a concentration of about 10^{-10} curie per litre, and that is very unlikely to be detrimental to health.

Once more the report of the Campaign has the great advantage of Mr. J. P. Lockhart-Mummery's editorship. It is not easy to present with any sequence work which is proceeding in many centres and often overlapping. The funds of the Campaign are steadily increasing—there was an excess of income over expenditure for the year ending July 31 last of over £50,000—in preparation for the increased "drive" in cancer research which is likely to follow the war.

COMMONWEALTH FUND FELLOWSHIPS

The Commonwealth Fund of New York, a philanthropic foundation existing since 1918, has established for British subjects a number of Fellowships tenable in the United States. The Fellowships were interrupted in 1941 by the war, but it is hoped to make a limited number of appointments in 1946. For these the following are eligible: Male candidates of British descent who are domiciled in the United Kingdom of Great Britain and Northern Ireland, and are graduates of recognized universities therein. Candidates must be over 23 and must not have attained the age of 35 on Sept. 1 of the year of award. These Fellowships are also open to candidates of British descent from the British Dominions distant from the United States, who have studied but not necessarily graduated at a university in the United Kingdom, and are graduates of a recognized university in a British Dominion or Colony, and who fulfil the conditions regarding age prescribed above. Such candidates need not show a permanent domicile in the United Kingdom, but must be available for interview in London in May.

Principles of Selection and Conditions of Tenure

The Committee of Award is prepared to consider applications from candidates who have shown marked ability during their university career, and who desire to extend their studies in an American university or other establishment. Special consideration will be given to the

experience acquired during war service. Experience in research and in postgraduate study, though a valuable, is in no sense a necessary qualification, nor is the Fellow bound to engage in original work, but evidence of proficiency in some recognized branch of university learning must be submitted and an approved course of study undertaken. The committee must be satisfied that the candidate is likely to profit by the Fellowship, and while primary consideration is given to intellectual ability, initiative, and actual or potential achievement, account is also taken of character, personality, and health. Other things being equal preference for awards will be given to men holding posts from which they can secure leave of absence, or to men who have definite vocational plans for a career. Candidates may state in order of preference the American university or other establishment at which they wish to study.

The committee hopes to announce early in May the names of candidates selected for interview, and to publish the awards before the end of that month. Arrangements will be made for medical examination of the candidates to be interviewed, and all expenses connected with the medical examination and interview will be borne by the Commonwealth Fund. The committee will consider only those who are prepared to give an undertaking that they will not accept another appointment until the expiration of the Fellowship, and that they will then return to some part of the British Empire and reside there for not less than two years, unless they are permitted to remain in the United States for reasons acceptable to the Fund. No one is eligible if he has already studied or worked in any educational or research institution in the United States for one or more academic years.

There is no fixed stipend, but the emolument attaching to each Fellowship, estimated at a minimum of approximately \$3,500 for twelve months, is calculated to cover the full expenses of residence, study, and travel in the United States during the year. Each Fellowship includes provision for: (a) an equipment allowance of \$100 and the cost of travel from the Fellow's home to the place of his assignment and return; (b) tuition, research expense, etc.; (c) a minimum of \$175 a month, paid quarterly, for living expenses for twelve months from the date of sailing (an advance of \$50 on the first quarterly payment is made); (d) an allowance of \$100 for travel during the Christmas holidays, if approved by the Fund; (e) an allowance of \$500 for travel in the United States at the end of the academic year, or at other times if approved by the Fund.

Tenure of a Fellowship involves an absence from Great Britain of twelve months, including a period of travel in the United States. Except for grave reasons, which must be stated in the application, Fellows will be expected to reach the United States not later than September of the year of award, or in the case of Fellows assigned to the University of California, in August. Though the standard tenure is twelve months, awards of an additional university year of nine months may be made, on application, to especially outstanding men who have valid reasons for such extensions, and whose applications are strongly supported. Certain conditions as regards recent vaccination are demanded by American universities, and candidates must be willing to comply with these conditions.

A Commonwealth Fund Fellowship is not tenable with a fellowship or scholarship from any other foundation established for a similar purpose. Candidates may, however, be applicants also for fellowships offered by such foundations, provided they do not accept more than one appointment. Speaking generally, no limitation is imposed on the subject of study to be undertaken during the tenure of the Fellowship. In the particular case of candidates in medicine, however, while research in the medical sciences, or in clinical medicine or surgery, is regarded as within the scheme, routine clinical work is excluded. Fellows are not required to follow either a degree or other ordinarily prescribed course in an American university; they are asked to submit their own programmes of work, but these will require the approval both of the Committee of Award and of the American institution. They may be permitted to change their scheme of work, or the institution at which they are studying, or to receive leave of absence, but only for reasons satisfactory to the Directors of the Commonwealth Fund. Although Fellows may be married, no provision is made for taking wives and children to the United States, and a Fellow may not marry during the tenure of his Fellowship.

All applications must be submitted on the prescribed form, and must be approved by the authorities of the college or university of which the candidate is, or has been, a member. They must reach Mr. Richard H. Simpson, Secretary, Commonwealth Fund Fellowships, 35, Portman Square, London, W.1, by Feb. 28, 1946, at latest. Further information can be obtained from the secretary, who will also supply application forms, and, so far as is possible, catalogues, bulletins, courses of study, etc., issued by various American universities.

Quinine may now be used for the induction of labour. In announcing this the Ministry of Health states that while the supply position of cinchona products still calls for strict economy it has improved sufficiently in the case of quinine for the Ministry of Supply to agree to this limited use.

NEW YEAR MEDICAL HONOURS

We have received from the Air Ministry the names of the following members of the Medical Branch of the R.A.F., included in the New Year Honours List but additional to those published last week at page 60.

C.B.E. (Military Division)

Air Commodore (Acting Air Vice-Marshal) KENNETH BIGGS, M.C., M.R.C.S., R.A.F.

Air Commodore (Acting Air Vice-Marshal) DUNCAN McLAREN, M.B., Ch.B., R.A.F.

Acting Air Commodore FREDERICK JOHN MURPHY, M.B., B.Ch., R.A.F.

Group Capt. VINCENT RUSSELL SMITH, M.R.C.S., R.A.F.

Acting Air Commodore WILLIAM JOHN GREAVES WALKER, M.R.C.S., R.A.F.

O.B.E. (Military Division)

Group Capt. JOHN FREDERICK BROMLEY, M.B., Ch.B., R.A.F.V.R.

Group Capt. ALBERT FREDERICK COOK, L.R.C.P.&S.I., R.A.F.

Squad. Ldr. LEONARD DUNCAN ALBERT HUSSEY, M.R.C.S., R.A.F.V.R.

Acting Squad. Ldr. WILLIAM LEONARD JAMES, M.R.C.S., R.A.F.V.R.

M.B.E. (Military Division)

Acting Squad. Ldr. WILLIAM OLIPHANT BAIRD, M.R.C.S., R.A.F.V.R.

Acting Squad. Ldr. FRANCIS JOHN HALLINAN, M.B., B.Ch., R.A.F.V.R.

Fl. Lieut. KENNETH MICHAEL HAY, M.B., B.Chir., R.A.F.V.R.

Fl. Lieut. ALEXANDER FINLAYSON LANG, M.B., Ch.B., R.A.F.V.R.

Squad Ldr. KENNETH ARTHUR WARING LAW, M.B., B.S., A.A.F.

A.F.C.

Wing Cmdr. JAMES RINTOUL CELLARS, M.B., Ch.B., R.A.F.

Mentioned in Dispatches

Group. Capt. V. S. Ewing, F. W. P. Dixon, M.B.E., and H. C. S. Pimblett, R.A.F.; Wing Cmdrs. H. E. Bellringer, H. F. Harvey, L. P. McCullagh, J. C. Taylor, E. B. Harvey, F. V. MacLaine, and A. Muir, R.A.F.; Wing Cmdrs. R. E. W. Fisher, R. C. Jackson, and H. P. R. Smith, A.F.C., R.A.F.O.; Wing Cmdrs. K. G. Bergin, T. A. W. Edwards, J. B. Methven, and J. V. Quinn, R.A.F.V.R.; Wing Cmdr. E. O. Walker, A.A.F.; Squad. Ldr. R. MacPherson, R.A.F.; Squad. Ldrs. B. A. J. Arthur, J. C. McC. Browne, F. R. Buckler, E. O. Evans, B. J. Frankenberg, M. O. J. Gibson, C. W. R. Rayne-Davis, E. P. S. Snell, J. Watson, P. A. Carrie, W. P. Greening, H. Halson, A. Hargreaves, G. G. Hartill, G. O. Horne, I. C. B. Pearce, E. E. Philipp, D. C. Russell, J. H. Spence, and T. F. Stewart, R.A.F.V.R.; Squad. Ldr. T. G. Davies, A.A.F.; Squad. Ldr. M. McLellan, R.A.F.O.; Squad. Ldr. Janet MacL. MacKay, R.A.F.; Fl. Lieuts. N. N. Blaxland, E. S. Brawn, H. D. Freeth, S. Gruber, M. J. Howlett, G. E. McFall, and R. M. S. Matthews, R.A.F.V.R.; Fl. Lieut. Caroline E. Nicholson, R.A.F.

Part II of the New Year Honours was published on Jan. 9, and included the names of the following members of the medical profession:

O.B.E. (Civil Division)

SAUL ADLER, M.B., Ch.B., M.R.C.P. Professor of Parasitology, Hadassah University, Palestine. For services to the Forces.

PERCY REGINALD BOLUS, M.B. Director of Medical Services, Ministry of Pensions.

JOHN LAIRD MCKENZIE BROWN, M.R.C.S. Medical Officer for Civil Defence, Metropolitan Essex.

WILFRID SAMUEL HAMILTON CAMPBELL, M.B., Ch.B., D.P.H. County Medical Officer, Lincolnshire (Lindsey) County Council. For services to civil defence.

DOUGLAS HENRY COLLINS, M.D. Medical Superintendent, Wharfedale Emergency Hospital, Sheffield.

MARY AYLWIN COTTON, M.B., B.S. Principal, Foreign Office. Recently employed in the Ministry of Economic Warfare.

ALEXANDER MILLAR MEER GRIERSON, M.D., D.P.H. Senior Assistant Medical Officer, Manchester. For services to civil defence.

LESLIE GEORGE HOUSDEN, M.D. Chairman, Mothercraft Training subcommittee, National Association of Maternity and Child Welfare Centres.

JOHN JETREY, M.D., F.R.C.S.Ed. Hospital Officer, Aberdeen, Department of Health for Scotland.

JAMES JOHNSTONE, M.B., Ch.B., D.P.H. Medical Superintendent, Haddington Hospital, Lanarkshire. For services to civil defence.

MAJOR ALEXANDER CAMPBELL WHITE KNOX, M.C., M.B., B.Ch. Assistant Commissioner, No. 1 District, St. John Ambulance Brigade.

IAN HYSLOP MCCLURE, M.B., Ch.B., F.R.C.S.Ed. Consultant Surgeon, County of Orkney. For services to civil defence.

WYLIE MCKISSOCK, M.S., F.R.C.S. Surgeon-in-charge, Neurosurgical Centre, Atkinson Morley Emergency Hospital, Wimbledon.

HENRY JOHN NIGHTINGALE, M.S., F.R.C.S. Senior Surgeon, Royal South Hants and Southampton Hospital, Emergency Medical Service.

WILLIAM POWELL PHILLIPS, M.R.C.S., D.P.H. Deputy Medical Officer of Health, Cardiff. For services to civil defence.

THOMAS POOLE, L.R.C.P.&S.Ed., L.R.F.P.S. Lately Medical Officer-in-charge, Military Prison and Detention Barracks, Riddrie, Glasgow.

SYDNEY CLIFFORD PRITCHARD, M.D. Medical Officer-in-charge, Hornsey Central Hospital, Emergency Medical Service.

STEPHEN JOHN SCURLOCK, M.C., M.D., M.S. Medical Superintendent, Ministry of Pensions.

IAN SCOTT SMILLIE, M.B., F.R.C.S.Ed., F.R.F.P.S. Orthopaedic Surgeon, Scottish Emergency Medical Service.

BYRCE MCCALL SMITH, M.B., Ch.B. Medical Superintendent, Victoria Infirmary, Glasgow. For services to civil defence.

THOMAS EDWIN PRYCE-TANNATT, M.B., B.S., D.P.H. Inspector of Salmon and Fresh Water Fisheries, Ministry of Agriculture and Fisheries.

GEOFFREY SYDNEY TODD, M.B., Ch.M., F.R.C.P. Medical Superintendent, King Edward VII Sanatorium. For services to civil defence.

BEATRICE ETHEL TURNER, M.B., B.S.Lond., F.R.C.S.Ed., F.R.C.O.G. Consultant, Obstetrician, Shardeloc's Emergency Maternity Hospital, Bucks.

JOHN THEODORE WHITELEY, M.B., Ch.B. Assistant Commissioner, Essex, St. John Ambulance Brigade.

M.B.E. (Civil Division)

Capt. CHARLES ANDRÉ BATHFIELD, G.M., M.R.C.S. Station Medical Officer, Air Transport Auxiliary.

WILLIAM FUNSTON BRYSON, M.B., B.Ch. Secretary, Enniskillen Hospitality Committee.

GLADYS ANYAN DANBY, L.M.S.S.A. County Superintendent, Somerset, St. John Ambulance Brigade.

MARGARET HOLLIDAY, F.R.C.S.I. Resident Medical Officer, Maternity Hospital for the Wives of Officers, Fulmer Chase, Buckinghamshire.

JOHN INGRAM, M.B., C.M. Medical Practitioner, Camp Reception Station, St. Agnes, Southern Command, War Office.

PHILIP INWALD, M.B., B.S. Medical Officer-in-charge, Civil Defence Mobile First Aid Unit, Islington.

EMMA MARY JOHNSTONE, L.R.C.P.&S.Ed., L.R.F.P.S. Lately Medical Officer-in-charge of Mobile Civil Defence Aid Post, Westminster.

ETHEL WINIFRED LEE, M.B., Ch.B. County Borough Organizer, Hastings, Women's Voluntary Services. For services to civil defence.

JOHN WILLIAM PARKS, M.D. Assistant Medical Officer, General Post Office.

ORDER OF ST. JOHN OF JERUSALEM

The *London Gazette* has announced the following promotions in and appointments to, the Venerable Order of the Hospital of St. John of Jerusalem:

As Knights: Lieut.-Gen. Sir James B. Hance, K.C.I.E., O.B.E., K.H.S. I.M.S., Col. W. E. R. Vickers, D.S.O., V.D., W. W. White, V.D., and J. R. Donaldson, and Dr. J. N. Morris, C.M.G. *As Commanders (Brothers):* Major-Gen. R. H. Candy, C.I.E., K.H.S., I.M.S., Major W. N. West-Watson, Messrs. A. G. Timbrell Fisher, M.C., and J. H. G. Robertson, C.B.E., V.D., and Drs. E. Hoerman, K. F. Lund, J. W. P. Harkness, C.M.G., O.B.E., and T. W. Meagher. *As Officers (Brothers):* Surg. Cmdrs. H. K. Corkill, O.B.E., R.N.Z.N., and W. A. Hopkins, O.B.E., Col. W. E. R. Dimond, C.I.E., O.B.E., I.M.S., Lieut.-Cols. S. Hunt, and E. H. Wood, and Lieut.-Col. P. A. Dargan, I.M.S., Majors S. H. Calnek, R.C.A.M.C., and J. F. Hamilton, Messrs. R. D. McKellar-Hall and C. G. Morice and Drs. O. T. J. C. de H. Clayre, C. R. Palmer, W. H. Pallett, J. P. Lowe, W. Murray, C. R. Corfield, E. R. Weaver-Adams, J. P. Prell, T. B. Gilchrist, A. Jueti, D. D. McCowan, H. W. Ward, J. R. Hanna, W. B. Fox, H. E. Moore, B. T. Parsons-Smith, W. E. Rutledge, E. H. M. Luke, E. R. Sibby, K. C. McGibbon, A. Rioux, W. W. Read, and H. J. Shone. *As Officer (Sister):* Dr. Hilda M. Davis. *As Serving Brothers:* Majors F. A. B. Sheppard, O.B.E., I.M.S., and G. Brown, and Drs. F. W. Furniss, W. Duncan, H. G. Watson, H. T. Chapman, S. B. Sutton, P. G. Commons, D. D. Coutts, E. W. Battle, T. H. Forrest, D.S.O., J. S. Cooper, N. G. H. Salmon, R. A. Dench, M.C., R. S. Renion, M.C., R. W. Pearson, M.C., E. Palmer, H. C. Williams, E. S. Johnson, M.C., J. A. Hislop, H. M. Jacobs, S. G. H. Gasson, B. J. Dudley, J. U. Page, J. B. Liggins, M. H. Box, A. B. Webster, J. K. Manson, G. E. Valentine, F. McLagen, A. M. Gillespie, O.B.E., and D. Lennox. *As Associate Serving Brothers:* Rai Sahib Dr. H. Prasad, Rao Sahab Dr. K. N. Nair, and Rai Sahib Dr. B. R. Kisaar. Mr. I. Blain, and Drs. S. M. Bangurnah, M.M. Bronstein, G. K. Ghosh, N. P. Chakraverty, A. K. Handekar, M. G. Kini, M.C., K. G. Ramabadrana, and B. B. Rai. *As Serving Sisters:* Drs. Lucie Van Dam, Olivia N. Walker, and Beatrice M. Joly. *As Associate Serving Sisters:* Drs. Rose Baranov and Hilde Ginsberg.

Reports of Societies

HUMAN GAMMA-GLOBULIN

A meeting of the Fever Group of the Society of Medical Officers of Health was held on Nov. 30, 1945, with Dr. M. MITTMAN in the chair.

Mr. B. R. RECORD, Ph.D. (Lister Institute), who opened the discussion, said that the realization that the various antibodies present in immune serum were associated with the globulin part of the serum, and indeed for the most part with a particular kind of globulin, had stimulated research into methods of separating human plasma into its component parts. The ultra-centrifuge and the electrophoresis apparatus had proved of the greatest value in this work. In the ultra-centrifuge, human plasma showed, broadly speaking, only two sedimenting boundaries, corresponding to a fast-sedimenting component, globulin, and a slower-sedimenting component, the albumin. In the electrophoresis apparatus, on the other hand, at blood pH the serum globulin appeared as at least three distinct components, designated α -, β -, and γ -globulin, in descending order of mobility. These different globulins had essentially the same molecular size and shape, and therefore sedimented as a single boundary in the ultra-centrifuge, but they had different ionizable groups, and therefore different rates of migration in an electric field. For this reason electrophoresis had become a most valuable analytical method in studies on the fractionation of plasma protein. Electrophoresis had not so far been developed for the separation of plasma components on a large scale. During the war Cohn and his co-workers had made an extensive study of the alcohol fractionation of human plasma, and this method was used in America for the large-scale preparation of various components of human plasma. Most of the antibody activity had been found to be associated with the γ -globulin fraction, which had been used clinically in the prophylaxis and treatment of measles.

Clinical Trials

Dr. W. GUNN (L.C.C.) said that the development of the clinical use of the various components of human plasma protein followed naturally Cohn's fundamental researches on their separation by high-speed centrifugalization and electrophoresis, and subsequent analysis of their biochemical and immunological characters. The main component, albumin, comprising 50 to 60% of the protein, was shown to have a very high osmotic activity. It was used on a considerable scale in a 25% solution to combat shock among American Service casualties. The globulin fraction originally designated Fraction II, now generally referred to as γ -globulin, represented about 11% of the total protein, and contained all the immune substances in the circulating blood. Though the amino-acid constitution of this fraction differed appreciably from that of α - and β -globulins, attempts to identify and isolate pure antibody, and to correlate its immunological properties with its chemical constitution, had hitherto failed.

Gamma-globulin was prepared in a specially buffered solution having a protein content of 16.5 \pm 1.5% in 5-cm. ampoules, each representing approximately 125 c.cm. of the parent plasma (from a pool obtained from several thousand donors). It was relatively stable compared with unaltered human serum and could be heated at 57° C. for four hours without loss of potency; this destroyed the agent of homologous serum jaundice. Samples of Cohn's original Fraction II, and several batches of γ -globulin prepared by different American manufacturers, were made available by the courtesy of the American Red Cross for clinical trial in this country.

Preliminary tests revealed that, volume for volume, γ -globulin was approximately twice as potent against measles as an average pooled convalescent serum. In the trials the recommended American dosage of 0.1 c.cm. per lb. (454 g.) body weight was followed; this was found sufficient for protection at ages under 1 year and over 5 years, but in the most susceptible age group, 1 to 5 years, protection failed in 10 to 15%. In nearly all there was moderate to pronounced attenuation, except in respect of one particular batch. The majority of the inoculations were given to home and hospital, or nursery, measles contacts in and around London, and in Glasgow, where the trials, carried out

under the supervision of Dr. T. Anderson at Knightswood Fever Hospital, gave substantially the same results. Some degree of success had been claimed for it by American workers in the prevention of infectious jaundice. The speaker referred to a small uncontrolled series of whooping-cough and chicken-pox cases successfully protected, and suggested that its use might be extended to the control of all the ordinary infectious diseases. In the treatment of measles its action had been found less certain, but more clear-cut results might be expected from the intravenous administration of the latest preparation, which Cohn had recently claimed to be free from risk.

Comparison with Convalescent Serum

Dr. NORMAN D. BEGG (L.C.C.) described a comparative test between γ -globulin and a dried, reconstituted, batch of convalescent measles serum. As modification of attack and not prevention was the aim, dosage had been pitched low. He summarized the experience of five outbreaks of measles in whooping-cough wards. Of 22 susceptible contacts injected with 2.5 c.cm. of the convalescent measles serum, 12 developed measles and only 4 of these were very sharply attenuated; 24 contacts of comparable ages from the same outbreaks injected with 1.2 c.cm. of γ -globulin produced 8 cases of measles, of which 6 were very much modified. The result of this limited experience indicated that γ -globulin had a measles antibody content at least twice that of convalescent measles serum, but further experience was necessary to fix dosage more precisely, and to decide on the importance of adjusting dosage to body weight at various ages.

For the prevention of measles in exposed contacts he had tried the American recommendation of 0.1 c.cm. per lb. body weight, with results which indicated that, with adequate preliminary field-testing of individual batches, γ -globulin would give high protection rates in this dosage. The results of treating established measles had been disappointing. One case in particular given 15 c.cm. of γ -globulin intramuscularly when the first Koplik's spots were visible, and 5½ hours before the skin eruption appeared, had later developed an entirely unmodified attack of measles.

Treatment of Poliomyelitis

Dr. W. H. KELLEHER (L.C.C.) said that the value of an α serum in the treatment of poliomyelitis was doubtful. He had abandoned the use of convalescent poliomyelitis serum for this purpose but decided to treat a series of cases with γ -globulin. The results in 10 cases of poliomyelitis, given an average dose of 34 c.cm., were entirely negative. Inconclusive results had been obtained in treating two cases of acute toxic polyneuritis and no improvement resulted from the use of γ -globulin in one case of acute myelitis. He had noted a failure to develop paralysis in poliomyelitis contacts with definite cerebrospinal-fluid changes who had been injected with γ -globulin, but this was a naturally occurring phenomenon and probably without significance. In reply to a question he said that he had not given γ -globulin intrathecally, and that there were physiological reasons against antibody reaching the anterior horn cells by that route.

Dr. H. J. PARISH (Beckenham) thought that the apparent complete failure of γ -globulin in the treatment of measles indicated that its antibody content might not be so high as was thought, and he suggested that it would be worth while preparing γ -globulin from convalescent measles serum in an attempt to produce a therapeutic measles serum.

Changes in the industrial service provided by the Royal Society for the Prevention of Accidents are to have effect in April. This is due to the ending of the arrangements made with the Ministry of Labour and National Service in 1940, by which a free wartime basic service of accident-prevention material was supplied to several thousand firms engaged on war work. Under the new arrangement the industrial side of the society will revert to a membership basis, though it will continue to work in the closest touch with the Government. Service will be provided on a co-operative, non-profit-making basis. A new membership scheme will replace the earlier one in operation up to 1940. As support from industry is increased, services will be extended and improved according to a definite plan which has been worked out during the past eighteen months. Notice of the change has been given to industrial undertakings in a circular issued from Terminal House, 52, Grosvenor Gardens, London, S.W.1.

Nutrition in Vienna

SIR,—The current ration scale in Vienna is designed to provide 1,550 calories for the lowest group of "normal consumers," 1,750 for "employees," 2,250 for workers, and 3,000 for heavy workers. The children's scale ranges from 1,000 to 1,550 calories. These rations represent an average diet per head of the population providing 1,931 calories daily. Perhaps I did not make it clear before that the tentative figure of 1,600 calories, which I ventured to print in my article published in the *Journal* of Dec. 15, 1945 (p. 839), as an estimate of the minimum energy intake which might be hoped to maintain the lowest ration group, would involve for the whole population a *per capita* consumption of almost exactly the 2,000 calories which you yourself in your leading article (p. 852) consider it reasonable to take as the "rock bottom" . . . minimum requirement needed to prevent disease and unrest."

The responsibility of anyone with a claim to knowledge of nutrition whose duty it is to try to influence food policy in Austria is a heavy one. How hard it is, therefore, to give nutritional advice as to what really is a minimum need when the scientific facts are themselves difficult to interpret, and when to include a "margin of safety" for one community and thus assess what one hopes is the physiological minimum too high, might well involve others who have equal claims on the same inadequate food supply in nutritional disaster.—I am, etc.,

Allied Commission for Austria, Vienna.

MAGNUS PYKE.

Tropical Medicine in the United Kingdom

SIR,—In view of the interest recently aroused in the present status of the teaching of tropical medicine in London and also in the United Kingdom (Dr. A. R. D. Adams and others (Dec. 22, p. 895) and Dr. G. Macdonald (Jan. 5, p. 26)) some statement about the facilities for the treatment of sufferers from tropical diseases in London may not be out of place.

In this respect it is unfortunate that the compilers of the otherwise excellent Goodenough report did not avail themselves of the advice of a single authority on tropical medicine in making their recommendations, and thus were led to conclusions which are generally unacceptable in this respect, though their concrete proposals for establishing links and outposts of the Tropical School in the Empire and of seconding special students to overseas hospitals is a policy I have constantly advocated.

I have been connected with the London School of Tropical Medicine for a great many years and on the staff of the Hospital for Tropical Diseases now for a quarter of a century. During this period I have been responsible to some extent for the clinical part of the teaching course, which has entailed the provision of suitable patients for clinical instruction of large postgraduate classes in tropical medicine. The Hospital for Tropical Diseases in Endsleigh Gardens, which had to be abandoned at the commencement of the war, suffered from the lack of popular and Governmental support. In the first place it could not be asserted that the building, which had been improvised, was exactly suitable for its purpose. While other countries—such as Holland, Belgium, Italy, and Germany—without such vital interests at stake all possessed well-equipped modern hospitals, this, the metropolis of the great and opulent British Empire, had to be content with a makeshift structure. It was, therefore, with something akin to a sense of shame that one had to conduct distinguished foreign visitors round a building which they had travelled far to see as the Mecca of tropical medicine and the monument to Sir Patrick Manson, the father of tropical medicine.

Nevertheless, inadequate as it may have been in equipment and appearance during the twenty years of its existence, it provided adequate clinical material for both teaching and research. This can be assessed by the number of scientific communications which emanated from members of the staff, and by the fact that some of them were of sufficient merit to gain their author the Fellowship of the Royal Society. The clinical observations also provided enough material for inclusion in successive editions of Manson's *Tropical Diseases*, which serves as the textbook for students not only in this country but also in the English-speaking world. Clinical demonstrations held twice weekly

were always well attended and often included other members of the profession in addition to the tropical class. In my own case most of the clinical conditions demonstrated were derived from my own practice, as this was for me by far the most fruitful field, when for several years little suitable material was forthcoming from other sources. It has therefore been abundantly proved that satisfactory clinical instruction can be given in London on the major tropical diseases, and this forms the groundwork for the general course in tropical medicine. Without the clinical aspect teaching in this subject becomes merely an academic "tinkling cymbal."

The members of the Colonial and other Government Services in India and elsewhere have to be catered for, in addition to the numerous commercial companies in Africa and other parts of the Tropics, seamen, ex-Service men, and many others.

In spite of the destruction during the recent dark years London is still regarded as the headquarters of medicine in the British Empire. Thither all critical and difficult cases have been dispatched for treatment, "blitzes," bombs, and submarines notwithstanding. Only those who have been responsible for the disposal of these unfortunates during the last six years can realize the difficulties that have had to be faced in the absence of some central institution where they could be cared for by those most competent to treat them. Had it not been for the services of the Albert Dock and Dreadnought Hospitals of the Seamen's Hospital Society this task would have been impossible. The practice of tropical medicine has become as important a specialty as orthopaedics, paediatrics, ophthalmology, or any other branch of medicine. It therefore deserves a suitable hospital worthy of the British Empire and of its immense tropical possessions. Tropical medicine has well merited support from the British Parliament and people. Achievements in this field have been of outstanding originality, both in days of peace and war, and many of the important discoveries have been made by British workers, who have done much for the security and prosperity of British possessions overseas.

This is the essence of the present problem. A start to remedy this defect has been made by the provision of a small hospital equipped by the Seamen's Hospital Society and supported by the Colonial Office which will shortly be opened in Devonshire Street. It is to be regarded merely as forming a nucleus from which important developments may be expected in the near future. I sincerely hope that this venture will be afforded that measure of support which it so richly deserves.—I am, etc.,

PHILIP MANSON-BAHR.

London, W.1.

Senior Physician, Hospital for Tropical Diseases;
Consultant to the Colonial Office and Crown
Agents for the Colonies.

SIR,—In his presidential address to the Royal Society of Tropical Medicine (*Journal*, Dec. 1, 1945, p. 774) Dr. C. M. Wenyon raised a matter of the greatest importance. That the facilities for the treatment of tropical diseases in this country are inadequate admits of no doubt whatever. As regards research, the importance is so obvious that it is self-evident; and although great progress has been made tropical medicine still offers an unrivalled and fruitful field for the research worker.

The need for training and research in the subject has a special claim on this country. In an Empire in which hundreds of thousands of square miles have already been rendered comparatively healthy and safe for Europeans, but which can only be so maintained by the work of men who have been specially trained, research and training should be an Imperial responsibility; and in view of future needs it is no exaggeration to say that the matter brooks no delay. There will be many doctors who in the course of their war service have "picked up" a knowledge of tropical disease which they did not possess before they joined up. But "picking up" an acquaintance is quite a different thing from the sound knowledge that comes from systematic training in it and its ancillary subjects of entomology, helminthology, protozoology, and bacteriology.

Usually the men who have trained in the subject have been those entering the Colonial Service or missionary field, or officers of H.M. Forces who desire instruction because of possible service overseas, or who wish to specialize. There is another aspect which needs consideration. In spite of all that the public has had the opportunity of reading in the press, it

is doubtful whether the enormous development of air transport in connexion with the war is generally realized. Already preparations are being made in almost every country to cope with the large volume of air travel which is confidently expected and will certainly occur, and this may have repercussions on the clinical horizon of this country. A comparison of incubation periods and speed of travel helps one to realize the chance of meeting with diseases in this country which may be common-places to the tropical practitioner but obscure and puzzling to his British colleagues; yet the immediate recognition of such diseases may have a most important bearing upon the public health. The quarantine period of cholera, for example, is five days—ample time for an infected person to reach this country from the East.

In my experience the average medical student is inclined to give rather perfunctory attention to diseases of warm climates, "because we don't get them here." It is perhaps natural that he should concentrate on the diseases which commonly occur within the clinical horizon of his own country. But the time is at hand when doctors must be prepared to recognize diseases which are liable to importation, and more serious instruction in diseases of warm climates should be included in the ordinary medical curriculum. At present there are many pieces missing from the great jig-saw puzzle that goes to make up the whole of medicine. The end of a war which has been waged not only against the enemy but against tropical disease is a fitting moment for putting the treatment and teaching of the subject on a foundation befitting the needs of the Empire.—I am, etc.,

Brockwood, Surrey

H. M. STANLEY TURNER.

Leprosy Control in India

SIR,—In the *Journal* of Oct. 6, 1945 (p. 466), reference is made to the proposed improvements to the present highly inadequate methods of leprosy control in India. The necessity for this is obvious to most doctors at present serving in the Far East. During a recent leave I visited the Purulia leper colony in Bihar, Eastern India, and I was able to see for myself the tragic shortcomings of present arrangements.

The Purulia leprosarium is a large hospital run by an inter-denominational set of missionaries, and is supported by voluntary contributions in the U.K. and elsewhere. It caters for between two and three hundred patients, who are warded according to the degree of the disease. Those with cutaneous leprosy, bullae and depigmented anaesthetic areas are ambulant and occupy a small set of bashes in the middle of the hospital, those with early gangrene and leprotic neuritis are given their own wards; and the final "arrests with deformity" when fitted with ingenious orthopaedic devices occupy their own section of the hospital. Naturally there is considerable overlap of these cases. Some distance from the hospital there is a nursery for apparently healthy children. These children have at least one parent in the colony. For all these people there is only one resident doctor, assisted by a Bihari compounder. He carries out all the routine treatment and surgery and valiantly attempts research with such equipment at his disposal. His job is an unenviable one. His facilities for research are limited, to say the least.

Leprosy is said to be a contagious disease, yet there appears to be very little authoritative control of the contagion. In almost every bazaar in India and Burma leprosy beggars ply their trade. Were the activities of these people restricted it is reasonable to suppose that the disease would decrease in incidence. Furthermore, more equipment should be made available to the research workers in the isolated hospitals. These measures together with suitable "popularization" by means of propaganda should undoubtedly help in controlling further what must surely be the most ravaging disease on earth.—I am, etc.,

D. ROSENBERG,
Major, R.A.M.C.

S.E.A.C.

Stethoscope versus X Rays

SIR,—I think that Dr. R. C. Hutchinson (Jan. 5, p. 31) has missed the most important point I tried to bring out in the discussion on stethoscope v. x rays at the Royal Society of Medicine. To put the matter quite simply, the fact is that, while detectable physical signs may or may not mean that there is active disease in the respiratory tract, the reverse is not true.

It is the case that with any early disease at its most treatable stage—and this does not apply to tuberculosis alone—there may be no abnormal signs of any sort, and it is in this type of case that x-ray examination is vital. The five senses in which Dr. Hutchinson would apparently prefer to place his faith are unfortunately not reliable in the recognition of early disease. The student is usually taught that physical signs mean disease, but the reverse is not impressed on him. It would not be possible to claim that the standard of early diagnosis is high, and I see no prospect of improvement until the value of routine chest radiology is recognized.

Nobody would deny that physical examination has its place, but the time has come when physical examination and radiology must be brought together and teaching must be based upon the intelligent combination of all methods of examination.—I am, etc.,

London, W.1.

JAMES MAXWELL.

SIR,—I read with interest the letter of Dr. R. Grenville-Mathers (Dec. 29, p. 941), but he did not mention any particular cause for his having written. I am a fairly assiduous reader of the *Journal*, but confess that I often give a miss to "Reports of Societies." Hence it was that Dr. R. C. Hutchinson's timely letter in the current issue (Jan. 5, p. 31), calling attention to the debate at the Royal Society of Medicine on "stethoscope versus x rays," took me by surprise: indeed it makes one rub one's eyes in astonishment.

When a member of this learned Society speaks of the stethoscope as useful "to find out whether a wrong name had been placed on the x-ray film or the wrong side of the body indicated," and then goes on to remark that the stethoscope "still lingered in the imagination of the patient; and medical men, even those who specialized in chest diseases, when they themselves had chest trouble wanted the colleague examining them to listen to the chest," and "it was difficult to avoid going through the gesture—it was not much more than that—of trying to hear vague mysterious sounds," one wonders how far he voices the opinion of the medical profession. Another doctor, as Dr. Hutchinson points out, expressed the same contempt in the extraordinary remark "Clinicians, however, should continue to use the stethoscope, because patients expect to see it." When statements like these are made one may be excused for coming to the conclusion that these individuals, even though they are members of a learned society such as the Royal Society of Medicine, have never attained real proficiency in the art of auscultation. I maintain that the recognition of post-tussive crepitations at one apex in a patient seen perhaps for the first time is as valuable a sign of pulmonary tubercle as the discovery of a shadow in an x-ray film. Why should anyone speak of them as "vague mysterious sounds" any more than one would speak of x-ray signs as "vague mysterious shadows," which, indeed, they sometimes are?

If this is to become the teaching of medical students, and clinical physical signs are to be discarded as worthless, then I feel sure that the criticism by another member at the meeting that "mass x rays had been positively dangerous in condemning sound persons to invalidism"—a belief which I have maintained before, in the course of an animated correspondence in the *Journal* on mass radiography—will be only too well confirmed. Possibly these devotees of the x ray will go one step further and declare that sputum examinations are superfluous: there is good evidence that this greatest essential of all is frequently neglected. In the correspondence during very recent years on mass radiography many radiologists of highest standing have raised a warning voice on the danger of relying on x-ray evidence alone, and also on the need for not only an expert radiologist, but also a first-class x-ray apparatus (a very expensive matter) for the diagnosis of the finer appearances on x-ray films of the thorax. But they are like voices crying in the wilderness.—I am, etc.,

Southborough, Tunbridge Wells.

E. WEATHERHEAD.

Physical Therapy in Mental Disorder

SIR,—Every right-minded psychiatrist deplores the indiscriminate use of electric convulsion therapy and prefrontal leucotomy, especially when they are employed as an escape from appropriate psychotherapy. But two facts must be borne in mind. (1) Mental disorder is not all psychogenic, nor is it

trained. Furthermore, midwives, tuberculosis nurses, Queen's nurses, and those holding health visitor's certificates have been forbidden to take industrial posts except in special circumstances. Dr. Aynsley may rest assured that the Minister of Labour in his survey did not leave State-registered nurses in industry unless he was satisfied that their skill and training were fully utilized, or that for various reasons they could not be usefully employed elsewhere.

Those with knowledge of the infinite variety of serious and potentially serious trauma and of the other health hazards in industry agree that the services of trained nurses during the war have been of the greatest possible value to our industries; we should be foolish indeed if we shut our eyes to this in view of the strenuous industrial effort required of us in the future.—I am, etc.,

London, W.16.

W. BLOOD,
Chairman, Association of Industrial
Medical Officers.

Purpuric Type of Textile Contact Dermatitis

SIR,—In the discussion on D.D.T. (Dec. 29, p. 933) I was interested to read Lieut.-Col. F. F. Hellier's remarks concerning the purpuric type of textile contact dermatitis apparently associated with the wearing of shirts impregnated with D.D.T. His statement—"The striking fact was that this extraordinary rash was something new to the B.L.A., it did not appear elsewhere, and the B.L.A. was the one Force which had gone out with impregnated shirts"—is not quite accurate, as I myself encountered many cases exactly similar occurring in soldiers serving in the C.M.F. Like Lieut.-Col. Hellier, I also suspected that the eruption was due to the impregnation of shirts with D.D.T. I discovered, however, that some of these patients had not been wearing shirts which had been impregnated, but that it never occurred in men wearing khaki drill shirts and was practically always seen in men wearing the woollen shirt with collar attached—i.e., the American olive-drab. Patch tests to the textile were positive, but negative to D.D.T. powder, while all other tests, such as the capillary resistance and blood examinations, were negative.

I have been informed by Dr. T. E. Anderson that in Scotland he saw similar cases in soldiers, and only last week a merchant seaman reported with a very similar eruption, apparently due to a new pair of blue dungarees. In his case there seemed no possibility of contact with D.D.T. in any form.—I am, etc.,

Edinburgh.

G. A. GRANT PETERKIN, M.B., F.R.C.P.Ed.

Spinal Analgesia

SIR,—It is very surprising that Mr. W. A. Fairclough (Dec. 8, 1945, p. 801) has been able to find ten cases of external rectus paresis following 2,021 spinal analgesics in a period of eighteen months. His figures certainly give an erroneous impression of the frequency of this particular complication, and I think it unlikely that the injection of the analgesic agent alone can have been responsible.

My experience of spinals extends for fifteen years. I have given all injections myself, and the convalescence of all patients has been under my personal supervision. I saw three cases of external rectus paresis in the first three years, when a variety of solutions were used—"stovaine," "spinothane," and 1/1,500 "nupercaine." One of the cases followed the injection of "nupercaine" and all cleared up rapidly. Since then I have used 1/1,500 "nupercaine" exclusively with increasingly rigorous attention to the preparation of syringes and needles. No external rectus paresis has occurred in a total of over 3,700 injections given during twelve years, and the complications suggesting meningeal irritation have been few.

Reports of catastrophes that have followed spinal analgesia seem to indicate that concentrated solutions are more likely to cause trouble. I think, however, that meticulous attention to the physical cleanliness of the apparatus is nearly as important as the selection of the solution if failures and complications are to be avoided. Absolute asepsis is, of course, assumed.

The enthusiasm inspired by the admirable operating conditions which spinal analgesics create must be tempered with a full appreciation of the very serious risk that attends their use in unsuitable cases. The risk is connected with the fall in blood

pressure which occurs in every case (not necessarily in proportion to the dose used or the area of analgesia produced), and the extreme variations in the capacity of patients to withstand it. Many cases of hyperpiesia, renal insufficiency, and late peritonitis or obstruction with marked distension react very badly; and the use of spinal analgesics in such cases will provide deaths on the table. Elderly patients with arteriosclerosis are likely to develop cerebral thromboses, either on the table or within 24 hours of the operation.

I think that the doses advised by Mr. McNeill Love (Dec. 22, p. 897) are rather small. They will work, no doubt, in most cases, but an irritating number of partial failures may occur which can be avoided by larger injections without increased risk. I give 17 to 18 c.cm. for all upper abdominal operations, and up to 20 c.cm. if the back is unusually long. A reliable dose for the lower abdomen is 14 c.cm., and smaller amounts may be used for the legs and perineum. On four occasions satisfactory analgesia failed to develop after injections of 14 to 18 c.cm., which presumably went into the epidural space. After waiting about twenty minutes the injection was repeated in each case with completely satisfactory results. One patient received 36 c.cm. and two others 32 c.cm. at one sitting, so I am inclined to discount the absorption of procaine as an element in collapse or complications.—I am, etc.,

County Hospital, Castiel, Co. Tipperary.

C. R. BOLAND.

Choice of Anaesthesia

SIR,—As regards choice of anaesthesia in abdominal surgery, apart from considerations of type of patient and operative requirements, this can be broadly classified according to the state of the patient, as follows: (a) fit for spinal, general, or local anaesthesia; (b) fit for general or local anaesthesia; (c) fit for local anaesthesia.

If the operative procedure merits its use, the surgeon should be given the choice of spinal analgesia. However, I think it quite wrong to try to persuade a surgeon, who has no enthusiasm for it, to accept spinal analgesia when an alternative technique can be equally well employed. (The surgeon's peace of mind during the operation is quite as important as, if not more important than, that of the anaesthetist.) On the other hand, when the surgeon states a preference for spinal analgesia he should be prepared, if necessary, to adapt his technique to suit the special requirements of the situation—e.g., gentle handling of the bowel and guarded conversation. Although the necessity for the latter is not present when a light, first-plane, general anaesthesia is induced, this may not always be desirable or practicable. The choice of the particular spinal analgesic to be employed, provided the surgical needs are satisfied, should rest with the anaesthetist. In the event of the surgeon demanding a particular analgesic agent which the anaesthetist conscientiously feels is contraindicated, then the surgeon should be prepared to administer it himself, and to accept all responsibility for any untoward event connected with its use.

Almost invariably in practice one finds that the surgeon is only too willing to leave anaesthetic matters to the anaesthetist, so that he may be free to give all his attention to the operation. Where there is proper team-work and understanding between the surgeon and his anaesthetist, the choice of the anaesthetic can usually be arrived at in a manner satisfactory to both parties, and this must redound to the advantage of the most important person concerned—namely, the patient.—I am, etc.,

KENNETH C. GRIGOR,
Anaesthetist, Southern General Hospital.

Glasgow.

Shock and Open Ether

SIR,—After reading Dr. Arthur Mills's letter on shock and open ether (Dec. 29, p. 938) I spent a leisure hour breathing through a Coxeter-Mushin closed-circuit machine with a basal oxygen flow of 500 c.cm. My pulse varied between 72 and 68 and my respirations between 16 and 14. My B.P. was not taken. I experienced slight discomfort towards the end due to the pressure of the face-mask, but otherwise no untoward effects during or after the inhalation. This is not surprising, as anaesthetists experienced with shocked cases assure us that the technique affording the best results is the closed-circuit using N₂O and O₂ with a high percentage of the latter and adding minimal quantities of cyclopropane if required. If the

breathing becomes unduly shallow the CO₂ absorbed can be partially or completely cut out of the circuit for a while. Furthermore, the technique for shocked cases should be adaptable to special requirements such as endotracheal administration and controlled respiration, and this is not possible with open ether.

If, however, ether and air is to be the first choice, is not the Oxford vaporizer the most accurate and most controllable means of administering it? The air can be enriched with oxygen through the special tap provided, and if the correct size of face-piece is chosen and correctly applied there is a gas-tight joint with no danger of hypoxia and with both eyes readily accessible for inspection and, if deemed necessary, for palpation. Few, however, are the anaesthetists who elicit the corneal reflex these days, and even fewer are the ophthalmologists who would give the practice their blessing.

With regard to the use of ether, there appear to be two sharply divided schools of thought among most anaesthetists and some surgeons. In the one ether is condemned and never used, while in the other it is the agent of choice. It may be helpful if both sides aired their views in the light of experience and up-to-date knowledge, and an authoritative and unbiased pronouncement made—I am, etc.

Frequency of Micturition after Injection of Haemorrhoids

SIR.—Dr. Kenneth Hazell's case of haematuria following an injection of haemorrhoids (Dec. 15, 1945, p. 864) calls to mind several patients that I have seen who developed disturbances of micturition after the same procedure. I can recall three such cases. They all complained of the onset of frequency of micturition within a few hours of the injection, in one case the symptom began within fifteen minutes of this treatment of piles; in another there was terminal haematuria and dysuria as well as frequency. I regarded all these instances as evidence of the connexion, through either the venous or lymphatic system between the lowest segment of the alimentary canal and the neck of the bladder. It is possible that Dr. Hazell's case is explicable along similar lines.

Probably a reversed process is demonstrated in the frequent incidence of piles in patients suffering from bladder-neck changes even without obstruction, or with different forms of posterior urethritis. I have seen many cases in which haemorrhoids have followed the above-mentioned urinary-tract conditions—I am, etc.

London, W 1

H. P. WINSBURY-WHITE

Varicose Ulceration

SIR.—I am glad to have seen so many letters in your correspondence columns lately on this subject. Apart from the few people who have specialized in varicose veins and ulceration, this subject has been sadly neglected by the average run of the medical profession.

I see on an average 50 cases of ulceration per week—cases sent to my clinic by other doctors. I have been appalled by the number of years that each individual patient has suffered from his ulcer before I see him. These patients have attempted under medical supervision to get their ulcers healed merely by the application of ointment and a silly piece of bandage just around the ulcer.

Unless the pathology of these ulcers is understood cure will never result. The primary causation of these ulcers is gravitational, and the only treatment that will effect the healing of the ulcer is to rid the limb of its congestion. It is therefore essential to study each limb individually, and, if necessary, to get rid of any causative or concomitant veins, either by appropriate injection or, in a few instances, by ligation of the internal saphenous vein where it enters into the deep femoral vein, together with the ligaturing of the five branches of the internal saphenous vein in that neighbourhood. In long-standing cases the injection or the ligation, or both treatments combined, will not, however, get rid of the brawny, oedematous swelling. This can be effected either by the unnecessary and absurd treatment of putting the patient to bed for three months or by tight bandaging with "elastoplast." I am aware that there are a few cases which will not tolerate "elastoplast" next to the skin but this difficulty is overcome as stated below.

My own technique in every case of ulceration is to apply "jelocat" to the ulcer base—occasionally in addition a sulphoanamide powder; on top of that the whole leg from the knee to below the knee is enveloped in "ichthoplast," then a pad of sponge-rubber with well-pared edges is applied over the ulcer and sometimes even several pads lying built-up over the ulcer. Then more "ichthoplast" is applied and finally "elastoplast" is applied with a back strap so as to prevent the lateral subsequent turns of "elastoplast" from cutting into the leg. Moreover, this "elastoplast" is applied from above downwards to prevent the rucking up of the "elastoplast," the sticking which would occur if it were applied from below upwards. Incidentally, this dodge was taught to me by my friend Mr. D. J. O'Sullivan Wright.

The usual story in these cases is to get an ulcer which has been existing for six years healed in two or three months, the bandages being changed on an average once a month. Once the ulcer is healed up, however, there arises the question of after-care of the ulcerous leg. Even when all possible has been done for the vein by injection and/or ligation as above described it is necessary that the patient should keep the leg supported for many months ahead, or even for the rest of his life, either by the daily application by the patient of an "elastoplast" bandage with a pad over the old ulcer site, exerting pressure, or in less serious cases by wearing an elastic stocking. I always tell patients also that standing is bad and walking is good, and to put their legs up in the evenings at home whenever possible on the sofa rather than have them dangling down—I am, etc.

Liverpool

STUART MCALISLAND

SIR.—With reference to previous correspondence on this subject, I feel that Dr. R. K. Brooks and other G.P.s who do likewise should be commended and encouraged to print their methods of treatment and experiences, as in this way the standard of general practice can be raised by helpful and accurate criticism from experts. On the contrary, there are some who see in such letters an occasion to divide and conquer and in this case in a manner which is only too true and valid that it is courteous. If consultants and others engaged in special practice were to engage in general practice or vice versa, from time to time many would learn a great deal worth knowing, apart from tolerance.

The subject can be summarized as follows. The treatment of varicose ulcers is primarily the treatment of an area of nutritional gangrene and secondarily the treatment of the accompanying varicose veins. The predisposing cause is lack of venous drainage and thus lack of adequate blood supply, existing cause usually a blow causing an abrasion and permitting entrance of bacteria, these latter proceed to destroy the devitalized area until better nourished tissue is reached.

Treatment (a) To increase the nutrition of the part affected by promoting venous drainage (b) to apply non-injurious bacteriostatics, for, as every medical schoolboy knows, sepsis is a potent barrier to repair. Venous drainage is promoted by: (1) elevating the limb (2) supporting the limb with elastic bandage or stockings etc.; (3) improving or removing the varicose veins to the full extent of the defective system concerned provided the deep venous system—supported as it is by muscles fascia etc.—is patent and healthy.

The method or methods adopted will depend upon the age, condition, and circumstances of the patient, but it is useless injecting veins in an ambulatory patient with a positive Trendelenburg sign—that is, a saphenous vein which fills from above when the patient assumes the erect position. In such cases the saphenous must be ligated and a portion excised at its entrance to the femoral vein. Furthermore, never inject a varicose vein in the region of the knee-joint. Finally, the elastic stocking is a valuable measure against recurrence of a healed ulcer and in treatment of varicose veins generally.—I am, etc.,

London, W 1

JOHN F. JENKINS.

SIR.—In the treatment of varicose ulcers there are three conditions to which attention must be paid: (1) venous stasis, (2) lymphatic stasis; (3) infection. All three must be treated before lasting cure can be obtained.

I have treated several thousand cases in the past fifteen years, and so far I have not failed to heal an ulcer, at least tem-

porarily. Some, alas! return years after with an ulceration in the old scar, generally from an injury, and these are the most difficult of all to cure. I still use the injection method for varicose veins, using Maingot's "twin" injection of lithocaine with quinine and urethane for large veins. With proper technique this gives excellent and lasting results. One injection at the saphenous opening will usually sclerose the whole of the internal saphenous vein as far as the ankle. For smaller veins I use "etalate."

For lymphatic stasis one must employ a bandage. But it is dangerous to apply an adhesive bandage directly to an ulcerated leg, for allergic dermatitis is sure to occur sooner or later and this may spread to the whole body. I apply an "ichthopaste" bandage from the foot to the knee. This must be very smoothly applied, letting the bandage run in the direction of its longitudinal fibres, and taking a half-turn when it is desired to bring it down the leg again. This is covered with a crêpe bandage, equally smoothly applied. The bandages are changed once a week or even once a fortnight, but the crêpe may be taken off for washing and a clean one applied by the patient if there is much discharge. As to local applications to the ulcer, I find that paints, lotions, and watery pastes are superior to ointments; of the paints I use 10% aqueous solution of brilliant green largely, but I also use triple dye and crystal violet in varying strengths. Sulphanilamide powder and sulphomerthiolate powder are useful if the ulcer is very dirty, but, as Dr. R. K. Brooks observes (p. 816), they cause an increase in the discharge and must be used with caution.

Finally, I believe that there is no cut-and-dried line of treatment which can be relied upon to cure every case. Each must be treated on its merits, or demerits, and only long experience can decide when a change of treatment is necessary. But if the above fundamental principles be followed, success will always be attained.—I am, etc.,

London, S.W.7.

R. SIMPSON HARVEY.

* * This correspondence is now closed.—ED., B.M.J.

Questionnaires, Past and Future

SIR,—I welcome the splendid suggestion contained in the excellent letter from Dr. R. Ritchie (Jan. 5, p. 33). I hope and urge that the matter of a fresh and unambiguous questionnaire, on the lines suggested by him, be taken up at once, with one additional and all-important question—namely, "Will you pledge support for the Negotiating Committee to stand firm on its 'Basic Principles'?" I have no doubt that if this is done the answers will show a vast majority of medical men to be strongly against the sort of service implied by the recent remarks of the Minister of Health.

The arrangements could easily and speedily be carried out by the secretaries of Divisions and the Central Medical War Committee. If it is to be done, it must be done at once, so that the profession can make a clear-cut decision and give its representatives a strong lead. This is needed because of the conclusions that can rightly be drawn from the remarks of the Minister. By implication our patients are to have a "free service given by directed doctors, whose compensation will be for public work only, though their private practices will, in fact, be stolen. And they will be tied to a service with a pittance of a pension, which they must either accept and go in, or reject and stay out. Their patients will be forced by high taxation, high rates, high cost of living, and payments for the cost of the new service, to accept it under financial duress, and few will be able to afford to stand out. This is the first move in the direction of nationalized medicine that will lead eventually but inevitably to the servile state. If we are united on our basic principles we can not only withstand the onslaught but produce a far better service for the people. Now is the time: let us wake up and stand up and fight for the freedom of our patients and our own integrity and just dues.—I am, etc.,

Camden, Road 22

S. F. LOGAN DAHNE.

SIR.—The excellent letter from Dr. Robert Ritchie is most timely and one can only hope may meet with the support it deserves and stimulate the practising profession to take effective action.

The course of events preceding the return of a new Ministry was sufficiently depressing and disheartening. What has happened since has filled us with despair. Most of us who struggled to take some active and effective part in the discussions and formulation of recommendations by the Negotiating Committee were sufficiently sickened by the policy of appeasement which permeated and undermined all attempts to present a united and determined front. At best "recommendations" and "suggestions" were put forward with a nauseating humility and deference for the consideration of the Minister of Health. At least this much was accomplished. Since the advent of the present Government the whole of even this little that had been done has collapsed like a pricked balloon. There are now no signs of any organized attempt to project and uphold what we know to be not only in the best interests of the public and profession but also matters vital to the very existence of our individual selves as the "working class" of the profession. The dictatorial pronouncements of the Minister of Health go unchallenged. Our apathy and ineptitude are in line with the same qualities displayed by the Opposition at Westminster. We have no programme or, if we have any, we seem to have no energy to put it into effect. It would seem that we have been beaten to the ropes and have thrown up the sponge. All and any dictatorial measures the present Government may think fit to introduce will go by default. We shall shortly be presented with a *fait accompli*, a very favourite method of dictators, and we shall be left to bemoan our Munich.

Dr. Ritchie very ably points out that there is no longer any doubt as to the Government's programme and intentions, and the time is now more than ripe for the profession to take a firm stand on fundamental principles and to answer "Yes" or "No" without fear or favour. Why this chicken-hearted fear of the emphatic "No"? Let us follow the example of New Zealand and refuse absolutely to co-operate unless our minimum demands are met. The result there was that the Government had to withdraw and think again. The questionnaire suggested by Dr. Ritchie would bring us out of the fog of irrelevant detail which has hitherto choked any attempt to arrive at an emphatic statement of minimum demands or fundamental policy into the sunlight where at least we shall know where we are, as well as making it clear to the present Ministry that we refuse to be trifled with. Even if we are ultimately defeated (I do not think so), at least we shall have regained something of our self-respect.—I am, etc.,

Oxford.

J. FRANKLAND WEST.

Domiciliary Midwifery and the Family Doctor

SIR,—Unless some such scheme to fuse the traditional functions of the family doctor and maternity hospitals, as suggested in the interesting letter by Mr. Arthur E. Brown (Jan. 5, p. 30), is speedily put into operation in this country, the further participation of the family doctor in midwifery will soon come to an end.

The trend towards institutional midwifery is now established and permanent; because the medical attendant realizes that no confinement can be trusted to be normal until it is safely over, and therefore appreciates conducting all cases under first-class conditions; the patient, in addition to the relief from domestic worries, realizes that an expert team and constant trained attendance are necessary for carrying out modern methods of analgesia and successful care of an abnormal case.

General-practitioner hospitals have been suggested in connexion with the new hospital service. Midwifery is surely a field in which they could be used to advantage under conditions described by Mr. Brown. Most patients would prefer to be attended by the man they know and who knows them, and who has attended them during the antenatal period; but, for lack of any alternative, more and more cases are being absorbed into large maternity hospitals, where they are not attended by a doctor. The general practitioner is thereby robbed of his midwifery, the very bed-rock of family practice, and is soon to be classed as incompetent to practise obstetrics in the new era. The pace of this will increase as further development of maternity hospitals closed to the general practitioner is planned, on a large scale, for rural and urban areas.—I am, etc.,

Warrington.

R. GUEST GORNALL, M.D.

Venereology

SIR,—I read with interest Lieut.-Col. Henry Richards's letter (Sept. 22, p. 414) denouncing the use of the word "venereologist," and I read Brig. T. E. Osmond's reply (Oct. 20, p. 556) with sympathy. As the latter says, many medical terms in common use are hybrids and mean something different from what would appear if their component parts were analysed. The unclassical word "antibody" has been made a classical example by the scorn of Quiller-Couch. It is a hybrid and does not refer to a substance which opposes or does harm to the body. It is, however, useful, and it has, moreover, remained. As a hybrid myself, being an obstetrician and a gynaecologist, I feel more than a little sympathy for other hybrids, even if they have not become members of a Royal College. Harmless and necessary, like Shylock's cat, are various hybrid vegetables and flowers, mules, and the English race. The recent attempt to erase the last from the face of the earth should give pause to all who would attack such hardy creatures or eliminate such words.

As for its inaccurate meaning, venereology, is no worse than "gonorrhoea," the purulent discharge of which does not proceed from the gonads, but which, as a word, is quite respectable and has remained unchallenged. If "venery" means the arts of love we cannot doubt that during the *pax Romana* they were not always respectable. In the many mansions which the temple of Venus contained there must surely have been one for those who suffered from their venery. Surely, therefore, a man may study any of the various manifestations of venery and be rightly accounted a venereologist.

The English language has never endured for long the lack of a useful word. It has stolen and changed without shame and, be it added, without detriment. It can do no harm, however, to explore the possibilities of a change, provided they are for the better—that is, not hybrids and not inaccurate. "Specialist in venereal disease" certainly could not be mistaken for an expert practitioner in the arts of love *par excellence* but the purists, whom we have to satisfy, might think he specialized in contracting rather than in curing these diseases. "Officer with a special knowledge of the diagnosis and treatment of venereal disease" is perhaps a little cumbersome and comes not trippingly off the tongue. Shall we have a synthetic word like "Nazi," "Seac," "Ensa," or "Unnra"? From "Medical officer with special knowledge of venereal disease" we have "Moskoviend." I doubt if this would leap into favour, and the less knowledgeable, who probably form the bulk of a "moskoviend's" clientele, might think a "moskoviend" was a Russian with something to sell. "Pox doctor" has been tried and found wanting, and, further, is inaccurate, as such medical officers do not necessarily teach. For India "pox wallah" could supplant the inaccuracy of "doctor," but one would have to mind one's "p's" and "b's" to avoid offence to the business community who are unfortunately often referred to as "box wallahs." It is unfortunate that the Greeks had no god who suffered as we mortals do. Perhaps Priapus, son of Aphrodite, did but kept the matter quiet. Lacking information and the means now of obtaining it, could he not be "deemed" to have had all possible venereal diseases—*honoris causa*, as it were? We could then call venereologists priapologists, leaving those who object to the former term to apologize for any confusion which might arise among those who regard priapism as Priapus's most distinctive feature. Until this or a better term is established I must confess that I shall use venereologist. I do not mind its being a hybrid, and venery nowadays is more of a misfortune than an art—I am, etc.,

G. BENJON THOMAS,

Major, I.M.S.

Professor of Midwifery, Madras Medical College

"Chronic Ear Disease"

SIR,—In their note on penicillin in chronic ear disease Surg. Cmdr. R. L. Kennedy and Surg. Lieut. J. W. Boland (Jan. 5, p. 13) seem to have classed together in one group the following separate ear diseases: (1) otitis externa with an intact tympanic membrane; (2) otitis externa in an ear with a dry perforation of the tympanic membrane; (3) otitis externa associated with suppurative middle-ear disease; (4) suppurative middle-ear disease. Their record would be of more value if each of these diseases had been described separately, and in the

cases with perforations of the tympanic membranes I should like to know the site and size of each perforation. I should think that aurists will be astonished at this innovation, or perhaps retrogression, of classifying so many separate pathological entities as "chronic ear disease."—I am, etc.,

C. DE W. GIBBS

Paracentesis and Myringotomy

SIR,—I read with full appreciation Mr. T. B. Jobson's observations (Jan. 5, p. 21) on the terms "myringotomy" and "paracentesis." Being rather inconstant on accuracy, I have for years impressed upon house-surgeons, and others, that the correct term for the operation designed to drain the middle ear is "myringotomy," the less satisfactory alternative being "paracentesis tympani" but not "paracentesis" alone. Mr. Jobson's interesting account of the derivations of the words will, I hope, help to correct an irritating slackness in terminology.—I am, etc.,

B. BRIMHAM

W. OGLEBY REID

SIR,—The question of what to call the small operation of puncturing the drum of the ear with a bent hypodermic needle on a syringe is, as Mr. T. B. Jobson says, most interesting. May I discuss one or two points in it?

The word myringotomy (cutting the drum), says the author, appears first in 1863 and again in 1875. Myringa is, he says, "a modern Latin word," meaning a membrane. To me its appearance and sound suggest very strongly its Greek descent. Compare syringa, used as a name for the lilac genus. This is derived from the Greek word *syrix*, meaning a tube or syringe, and it is applied to lilac on account of the shape of the flowers. Syringitis (inflammation of the Eustachian tube) is derived from the same word. I have a medical vocabulary by Dr. Fowler, published 1875 which gives the word myringitis but not myringotomy. It gives the derivation of the word myringa as a barbarism for *membrana tympani*. It would not, I agree, be right to call the operation myringotomy, as it is not a cutting of the drum.

I am suggested that the operation should be called "paracentesis," a piercing through, a word some 2,000 years old or more. The verb *parakenteo* (*para*=through and *kenteo*=I pierce) meant in those times "I tap for urine." The *para* does not give the idea of piercing completely, or right through, so I suggest that the Greek word *di-* would be better, giving us *diacentesis* as the needle passes completely through the drum. I suggest the name for the operation should be *syngomyringodi-centesis*, or for busy otologists *S.M. di-centesis*. A syringe has a function—to eject or withdraw fluid—so that the name I venture to propound tells us what is done and how.—I am, etc.,

G. GIBBS

J. K. MULLIGAN

"Cord Round the Neck"

SIR,—May I try to lay another small tree in the forest of obstetric superstition? During the past few months I have heard of four cases of stillborn babies in which the death at birth has been attributed to the "cord being round its neck." In all my years of obstetrics I have complacently accepted this explanation, but is it wholly, or even partly, true? It is certainly a facile excuse and one meekly accepted by the bereaved parents.

Presumably the foetus dies from asphyxia because the cord is so tight around its neck that it cannot breathe. This explanation is completely untenable for two reasons. First, the constriction can be removed before the baby even attempts to breathe, and, secondly, the rings of the full-term trachea are harder than the cord, and so it must be the cord which is compressed, not the airway. This brings me to the other explanation generally given—that the foetus dies because the placental blood is prevented from arriving through a compressed or stretched cord. It does not become stretched because the uterus and placenta descend with the foetus. What compresses it? Not its own coiling, for were that so the foetus must have died long before; not its passage through the pelvis, for it is protected by the head. To say that it is pressed on by the chin in flexion is to stretch credulity too far.

I can understand intra-uterine amputations caused by a loop of cord or even intra-uterine death (DeLee gives a picture of one), but I cannot see why the coiling of the cord round the

foetal neck should cause stillbirth. Although the argument is unscientific, all of us have delivered many live babies with one or more loops of cord round the neck. I personally have never had a stillbirth from this cause. In the four cases I have mentioned one infant died undoubtedly from toxæmia, one from an attempt to turn a breech under deep anaesthesia, and the histories of the others were incomplete. I do suggest, therefore, that we might review our ideas on this subject, and the diagnosis of "cord round the neck" should be regarded with grave obstetric doubt.—I am, etc..

London, W.1.

MORTIMER REDDINGTON.

Case of Adder Bite

SIR,—I was interested to read some correspondence in your columns a little while ago about adder bites. It seemed that the number of recorded cases was small, and it may therefore be of some interest to give a short account of a case that occurred recently in the Isle of Wight.

On Oct. 5, 1945, a warm sunny day, a man was picking up chest-nuts in Parkhurst Forest, when at about 1.35 p.m. he was bitten by a snake, which was clearly identified as being a large adder. The incident occurred near a factory where there is a division of the St. John Ambulance Brigade, and within a few minutes—certainly not longer than ten minutes—he was receiving attention from members of the Saro (I.W.) No. 2 Ambulance Division. The bite was on the first finger of the right hand in the region of the first phalangeal joint. A 1-inch (2.5 cm.) bandage was applied to the base of the finger as a constriction and the wound sucked. The patient was placed in a recumbent position and encouraged to keep calm. By this time slight swelling had taken place. A hot solution of potassium permanganate was applied and bleeding induced by gentle squeezing. About ten minutes after treatment a heavy sweat appeared on the patient's brow, and a dose of sal volatile was given, after which his condition improved.

No doctor was available, so the patient was taken by car to St. Mary's Hospital, Newport, the constriction on the finger having been released and reapplied before the commencement of the journey. On reaching the hospital the patient appeared quite calm, only complaining of pain at the seat of the injury. When the hospital sister examined the finger on arrival, about 25 minutes after commencement of treatment, the swelling had travelled approximately 2 in. (5 cm.) upwards. The patient was put to bed with applications of hot potassium permanganate, and later had an injection of 10 c.cm. "sérum antivénimeux" (Institut Pasteur de Paris).

The following day a large blister appeared on the top of the finger and was incised. On Oct. 10 the patient's condition was satisfactory, and he was due for discharge the next day. On Oct. 11, however, he complained of intense irritation of most parts of the body, with swelling of the face and vomiting. He was discharged on Oct. 13. After discharge he complained of "lack of feeling and sensation" from the site of the wound to the top of the finger. On Nov. 27 this was said to be gradually improving.

I am indebted to Divisional Superintendent W. E. Peach, S.J.A.B., for details of this report.—I am, etc.,

Wootton Bridge, I.O.W.

F. R. B. H. KENNEDY.

Obituary

Staffordshire in general and the Black Country in particular (writes A. B. D.) are poorer and emptier places by the passing of Dr. LOCKHART LOWE on Sept. 3. Doing his daily round and performing the common task until a week before his death, he became tired for the first time in his life and gracefully led out from the turmoil which had always surrounded him. Born on April 1, 1870, Lowe was a Birmingham man. He was educated at his father's private school in Handsworth and had his medical training at Mason's College. In 1894 he took the Conjoint diplomas and a house appointment at the Paddington Infirmary. He then returned to the Midlands to assist Dr. Jonathan Hobbs at Clent. Thence he came to Walsall as partner to Dr. Caddick. He retained the Darlaston branch of the practice, and lived and worked there until his death. It is given to few general practitioners to serve the public for over fifty years, but this Lowe did, very ably and very pleasantly. His charm of manner and unflinching temperament endeared him to all his patients, commanded respect from the public and the esteem of his brother-practitioners. Though entirely unassuming and of retiring disposition he was a man of many parts. In his youth he had been a well-known Midland lacrosse

player. He played a very good game of tennis until he reached 70 years of age. He was a born musician and could play any orchestral instrument; as a pianist he was an infant prodigy, giving a recital in Birmingham Town Hall before reaching his teens. Among his friends he was a trusted adviser, and his wide experience was of great value in committee work, for which he had a flair. No B.M.A. meeting was complete without him, and he missed few. He was an original member of the Walsall Local Medical and Panel Committee. He was chairman of this committee and also of the Walsall and Lichfield Division several times. In July, 1929, he was elected to the Staffs County Panel Committee, of which he became honorary secretary in 1937. On many occasions he attended Panel Conferences in London as a county representative. In 1937 he also became a member of the Staffordshire Insurance Committee. In Darlaston he held many appointments, including those of police surgeon, social welfare medical officer, and factory appointments. He was intimately associated with the St. John Ambulance and Red Cross organizations. He was surgeon to the Walsall and District Corps, and an able lecturer and examiner to both movements. When war broke out he was immediately active in organizing Civil Defence services. In addition to local committee work he was M.O. and instructor to a first-aid post. As chairman of war charity committees he was largely responsible for collecting many thousands of pounds for the Red Cross and other charities. His wife, who had been a chronic sufferer, predeceased him by several years. Dr. Lowe leaves two married daughters. Walsall and Lichfield Division and the Staffordshire Branch of the B.M.A. bid farewell to a very dear elder brother.

Dr. ALICE JANET McLAREN, who died on Dec. 20 at Crail, Fifeshire, at the age of 85, was the first woman gynaecologist in Glasgow, and as joint founder and first medical superintendent of the Redlands Hospital for Women played a big part in the training and guidance of many medical women. A native of Edinburgh, Dr. McLaren had her training at the London School of Medicine for Women, and graduated M.B., with first-class honours in medicine, in 1890, taking the B.S. a year later, and the M.D. in 1893, after serving as resident house-physician at Leith General Hospital. She then became assistant to the surgeon of the Glasgow Lock Hospital, and later as one of the first two women to be appointed to the Board of Management she did much to effect reorganization and improvement of that institution. Later she was appointed assistant surgeon at the Glasgow Royal Samaritan Hospital, being the first woman to be elected to the visiting staff of a hospital in Glasgow. It was in 1903 that she took a leading part in founding the Glasgow Women's Private Hospital, now the Redlands Hospital for Women, and there she worked at first as gynaecological surgeon. Dr. Alice McLaren was also consulting gynaecologist to the Royal Mental Hospital and carried on during four decades a large private practice. When she retired from active work in 1932 a presentation was made to her in Queen Margaret College, Glasgow.

We regret to announce that Dr. WILLIAM HOWARD UNWIN died at Timaru, New Zealand, on Christmas Day in his 75th year. He was a student of Charing Cross Hospital, qualified in 1898, and took the F.R.C.S. diploma in 1901. At the Final M.B.Lond. examination he won the University scholarship and gold medal in obstetric medicine, and proceeded M.D. in 1903 after serving as house-surgeon at Charing Cross. During the war of 1914-18 Dr. Unwin was officer in charge of the surgical division of No. 2 N.Z. General Hospital at Walton-on-Thames. He held office as honorary secretary of the South Canterbury Division of the B.M.A. in 1922-4 and was elected president of the New Zealand Branch in 1944, having represented the Branch at the Centenary Meeting in London in 1932 and at the Plymouth Meeting in 1938.

Dr. EDWIN SWAINSON MILLER, surgeon captain, R.N. (retired), died at Brentwood, Essex, on Dec. 30, 1945, aged 76. He was the son of William Charles Miller, of Liverpool, and was educated at Shrewsbury School and at Liverpool University, whence he qualified as M.B., Ch.B. Vict. in 1893. After serving as house-surgeon at the Royal Infirmary, Liverpool, he entered the Medical Service of the Royal Navy, and retired in 1920 with the rank of surgeon captain. He then practised in Brentwood for a quarter of a century, and only finally relinquished this when his health began to fail last year. Dr. Miller married in 1915 Miss Helen Beatrice Liardet, who survives him with two sons, the elder of whom, Dr. P. J. Miller, is a member of his father's profession. Throughout his twenty-five years in Brentwood he was a member of the staff of the District Hospital. He joined the B.M.A. in 1897.

News has been received of the sudden death on Dec. 30 at Bhopal, India, of Lady BHORE, wife of Sir Joseph Bhore, K.C.S.I., K.C.I.E. Margaret Wilkie Stott, elder daughter of Joseph Stott, of West Newport, Fifeshire, was born at Dundee on June 20, 1884, and from the Fife Academy went to St. Andrews Medical College, Dundee, graduating M.B., B.Ch. St. Andrews in 1907. After a year as an assistant in general practice at Preston she went out to India as M.O. to the Berhampore Baptist Missionary Hospital. Her husband, whom she married in 1911, has been a distinguished member of the Indian Civil Service and held important Government offices before his appointment to the Governor-General's Executive Council. Lady Bhore won a Kaisari-Hind Medal and was awarded the O.B.E. in 1944.

By the death of Dr. J. PRICE WILLIAMS on Jan. 1 Swinton and Pendlebury has lost an outstanding personality. He was educated at Dentstone College and Manchester, and obtained the M.R.C.S. and L.R.C.P. in 1888, the M.B.Lond., with honours in forensic medicine, in 1889, the M.D.Lond. in 1892, and the B.Sc.Vict. in 1904. After working as assistant resident M.O. at Morsel Fever Hospital he became public vaccinator for Swinton and Pendlebury, and medical officer to the Post Office. He leaves a widow and two children: Dr. E. Williams, who practises at Barnsley, Yorks, and a daughter married to Col. R. Raymond, I.M.S., who lives in Australia. Dr. Price Williams gave up practice ten years ago to reside at Bramhall and Ambleside. He held various offices: chairman of Lanes Area 22 Local Medical Committee and later Area 22 representative on the Lanes Panel Committee. He was a member of the committee of the Salford Division of the British Medical Association, which he joined in 1900. During his 47 years as a general practitioner he endeared himself to his friends and patients and earned the regard and good will of his fellow-practitioners, who on his retirement presented him with a writing-desk to mark their appreciation and their esteem of him as a leader of the local medical profession. In his younger days he was a playing member of the Swinton Cricket Club, a good chess and billiards player, and fond of bridge, music, and the drama.

Dr. CHARLES HARRY EAST, who died in retirement on Dec. 22 at his home at Bagshot, Surrey, aged 84, studied for the medical profession at King's College, London. He took the L.S.A. in 1884, the M.R.C.S. in 1886, the M.B., B.S. of Durham University in 1887, and proceeded to the M.D. degree in 1890. At King's College Hospital he was house-surgeon to Lord Lister, and medical registrar and tutor, and was also assistant demonstrator of anatomy at King's College. Dr. East practised for a short period in Monmouthshire, and then settled at Great Malvern until his retirement in 1921.

The following well-known medical men have died abroad: Dr. F. JAYLE, an eminent Paris gynaecologist and former editor of *La Presse Médicale*; Dr. RAFAEL A. BULLRICH, a cardiologist of Buenos Aires, aged 67; and Dr. MARIANO ALURRALDE, professor of clinical neurology at the Buenos Aires faculty of medicine.

Universities and Colleges

UNIVERSITY OF EDINBURGH

Dr. Douglas Guthrie, lecturer on the History of Medicine, will deliver an introductory lecture in the Pollock Memorial Hall, Bristo Street, Edinburgh, on Tuesday, Jan. 22, at 5 p.m., on "The Search for a Philosophy of Medicine."

Sir Alexander Fleming, F.R.S., will deliver the Cameron Prize Lecture on "Penicillin—its Origin and Use" in the anatomy lecture theatre, University New Buildings, Teviot Place, Edinburgh, on Friday, Feb. 22, at 5 p.m. All students and graduates are invited to attend.

QUEEN'S UNIVERSITY, BELFAST

The following candidates have been approved at the examinations indicated:

M.B., B.Ch., B.A.O.—*R. D. N. Blair, *B. T. Crymble, *T. H. Flewett, *C. S. Lindsay, *C. B. McClintock, *J. O. R. Stewart, J. Beckett, L. C. Bell, H. J. Blackwood, J. F. Booth, E. R. Broadberry, C. Burns, H. MacD. Cameron, E. A. Casement, S. P. C. Casey, J. B. Cromie, Joan P. D'Arcy, A. W. Dickie, P. F. Donnelly, F. G. Dove, P. Farnan, W. J. Forsythe, Rosemary Fullerton, W. R. Gilmore, A. L. Griffith, D. J. W. Hume, G. V. Hinds, J. A. Howard, T. V. Humphreys, R. Jacobs, F. R. Johnson, S. Kay, S. H. S. Love, J. Lowry, Mary C. McClure, Florence McKinstry, T. A. I. McQuay, D. Maguire, J. N. Montgomery, W. E. Parkes, J. E. Pyper, J. I. Rolston, S. Sloan, Maude Stevenson, G. K. Thomas, N. D. Wright.

The Services

The honour of commandship of the Legion of Merit has been conferred upon Air Marshal Sir Harold Whittingham, K.C.B., K.B.E., LL.D., K.H.P., F.R.C.P., Director-General of Medical Services, R.A.F., by the President of the United States of America. Capt. S. P. Dutt, I.A.M.C., has been awarded the M.C. in recognition of gallant and distinguished services in the Middle East in 1942.

Surg. Cmdr. W. McO. Macgregor, O.B.E., V.D., and Temp. Surg. Lieut. T. E. Barwell and A. F. Ross, R.N.A.R., have been mentioned in dispatches.

Acting Surg. Lieut.-Cmdr. L. E. Prowse, R.C.N.A.R., has been awarded a commendation.

The following have been mentioned in dispatches in recognition of gallant and distinguished services in Italy: Lieut.-Col. (Acting Col.) C. A. McIntosh; Lieut.-Cols. W. H. P. Hill and J. S. McCannell, O.B.E.; Majors L. W. Bassett, T. G. Fyfe, and J. F. Nicholson; Capt. M. L. Harley, M. Lerner, M.C., R. M. Levine, H. G. Metcalfe, R. F. M. Meyers, W. A. Reed, and W. H. White; Lieut. E. Shaw, R.C.A.M.C.

The following have been mentioned in dispatches in recognition of gallant and distinguished services in Burma: Col. (Temp.) N. P. Breden, and W. J. Officer, O.B.E.; Col. (Acting) M. MacR. Paterson, O.B.E. (killed in action); Lieut.-Cols. (Temp.) D. G. Adamson, J. McK. Johnstone, W. G. MacDougall, A. J. Martin, O.B.E., D. J. O'Ryan, R. P. Smyth, O.B.E., J. A. Strong, M.B.E., and W. G. Sutcliffe; Lieut.-Col. (Acting) W. L. Putter; Majors (Temp.) T. Fitt, W. R. N. Friel, T. Griffiths, A. J. Moffett, H. G. Page, R. A. Philip, A. E. G. Ridgway, J. G. Scott, M.B.E., R. K. A. Van Someren, and R. Wigglesworth; Capt. D. M. P. Clarke, H. D. Cockburn, M.C., L. R. Dalton, W. Drummond, J. A. Farrell, P. E. Helme, M. H. Hughes, J. F. Mark, C. M. McGeoch, J. W. F. Richardson, M. F. Ronayne, I. H. Stewart, and A. H. Williams; Capt. (Temp.) J. A. McPherson; Capt. (Acting) P. R. Robinson, R.A.M.C. Col. (Acting) J. D. Grant, G. B. Jackson, and V. E. M. Lee; Lieut.-Cols. (Temp.) L. H. Carter, and M. B. Menon; Major (Temp.) A. C. Greene; Capt. B. Singh, C. T. Shah, E. B. Naug, M.C., B. J. Pereira, J. M. P. o, H. A. Press, B. Rowlett, and S. N. Sinha; I.M.S. Lieut.-Col. (Temp.) J. Reidy; Lieut.-Col. G. V. Chappell; Major (Temp.) A. E. R. Coombes; Capt. M. P. U. V. Raja, M. L. Panyan, M.B.E., and V. Rangaswami; Lieut. C. R. Narayan, P. Jagannatham, M. A. Jabbar, and S. S. Roy; Subadars K. Ram and Nanohal, Jamadars M. N. Khan and P. Singh, I.A.M.C.; Major (Temp.) J. A. Hides, R.C.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Officially reported killed in action at Singapore, Feb. 15, 1942—Capt. William Lee Donaldson, Medical Officer, S.S.V.F.

DEATHS IN THE SERVICES

Lieut.-Col. HERBERT EDWARD DRAKE-BROCKMAN died on Dec. 29 in Jersey, after a short illness, at the ripe age of 80. He was one of the distinguished Indian Medical Service officers of that name, and was born at Cawnpore on Feb. 14, 1865. He was educated at St. George's Hospital, passed the English Conjoint final examinations in 1887 and the F.R.C.S. in 1889. He entered the I.M.S. in 1883, and distinguished himself at Noddy by carrying off the Herbert exhibition and medals in tropical medicine and in hygiene. After completing his service on the military side he entered the political department, and held at different times the important posts of Residency Surgeon at Hyderabad, East Rajputana, Kashmir, and West Rajputana. When at Hyderabad he held the responsible positions of Director of the Medical Department and Sanitary Commissioner for H.H. the Nizam's Dominions, and principal of and lecturer on ophthalmic surgery in the Hyderabad Medical School. In all these positions he inspired the trust and confidence of the rulers of the States he served so faithfully. While in India he published a medico-topographical gazetteer of the Eastern Rajputana States, a work on the anthropometry of castes and tribes of the North-West Province and Oudh (now the United Provinces), and a report on a plague epidemic in the Hyderabad State, 1915. He also saw active service on the North-West Frontier with the Miranzai Expedition of 1891. After his retirement in 1920 Drake-Brockman became medical officer in charge of a tropical diseases clinic and oculist under the Ministry of Pensions at Southampton. He was a member of the Ophthalmological Society of Great Britain, that being his favourite subject. He joined the British Medical Association in 1889.

In an effort to increase the production of penicillin, for which the world-wide demand far exceeds the present manufacturing capacity, the U.S. Civilian Production Administration on Dec. 26 announced that it will give special priorities assistance to producers.

No. 52

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 29.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

Stillbirths	205	21	36	—	—	181	15	25	—	—
Rate per 1,000 total births (including stillbirths)	—	—	44	—	—	—	31	—	—	—

* Returns for infectious diseases for Eire include those for the previous week.
 * Measles and whooping-cough are not notifiable in Scotland, and the returns are for an approximate year only.
 * Includes primary form for England and Wales, London (administrative county), and Northern Ireland.
 * Includes puerperal fever for England and Wales and Eire.
 * On a basis of the 1931 census of population, birth and death rates for Northern Ireland are not available.

EPIDEMIOLOGICAL NOTES

Influenza and Winter Temperatures

Is it true, as has recently been suggested in the daily press, that an influenza epidemic may be avoided if we have a hard winter? This belief appears to be widespread, and it seemed worth while reviewing past experience to see whether there is in fact any justifiable foundation for such an opinion.

The usual trend of influenza mortality—a very slow rise in the late autumn with a more rapid increase in late December and early January—does suggest a seasonal factor. Although influenza has appeared in epidemic form throughout history, it is only in recent years that the disease has become an important annual cause of death in this country. During the decade 1880-9 the annual death rate was as low as 2 to 5 per million. After the epidemic of 1891-2 the incidence of influenza remained high, but between 1901 and 1917 the death rate never exceeded 293 per million; in nine of the seventeen years it was below 200. There was a further increase in the endemic level after the pandemic of 1918-19; in only six of the nineteen years from 1920 to 1938 was the death rate below 200 per million, and in four years it was more than 500. Any deduction concerning the relationship of hard winters to influenza epidemics must be based on the later period, in which the outbreaks are in sharper contrast than in the earlier periods. Since most deaths from influenza are registered in the first quarter of the year, this period determines the annual rate. The following table gives the deviation of temperature from the normal daily mean for October to February (normal values being based on the 35 years, 1891-1915) for the years when the crude death rate per million exceeded 400, and for the years when the death rate was less than 200.

Years of High Mortality

	1937	1933	1929	1927	1924	1922
Death rate per million	454	569	734	567	489	563

Mean Deviation of Temperature from Normal Daily Mean

	1936-7	1932-3	1928-9	1926-7	1923-4	1921-2
October	-0.8	-0.8	+1.6	-2.2	+0.5	+6.4
November	-0.1	+0.9	+2.8	-0.2	-4.9	-2.3
December	+1.6	+2.5	-1.0	-0.2	-1.1	+3.5
January	+1.6	-1.5	-3.1	+1.9	+1.8	+0.2
February	+2.3	+0.5	-6.2	+0.5	-1.4	+1.0

Years of Low Mortality

	1938	1936	1935	1934	1930	1928
Death rate per million	118	148	182	139	126	196

Mean Deviation of Temperature from Normal Daily Mean

	1937-8	1935-6	1934-5	1933-4	1929-30	1927-8
October	+1.0	-0.4	+1.1	+1.7	+0.6	+1.7
November	-1.0	+1.5	+0.6	-0.7	+0.9	-0.3
December	-2.8	-2.5	+5.9	-4.5	+2.8	-3.9
January	+2.6	-0.8	+0.6	+0.1	+3.9	+2.9
February	+1.3	-2.7	+2.9	-0.3	-2.1	+3.4

These figures afford no evidence that a hard winter prevents influenza epidemics. If a deviation of +1.5 or more is taken as a warm month, and -1.5 or less as a cold month, we find that each of the five months appear with equal frequency as warm months of high and of low mortality. January was warm in three of the low-mortality years and in three years when the influenza mortality was high. All the four cold Decembers were followed by a low mortality, but when November and January were cold on two occasions the mortality was high. The outbreaks of 1929 and 1930 provide an interesting contrast: the former was the largest death rate recorded since 1918-19 and the latter was the lowest but one. January and February of 1929 were noted for exceptional cold—it was the severest winter since the great frost of 1895. In January, 1930, the temperatures recorded at Greenwich were the highest since 1841. Despite the unusual severity of the winter in 1929 the deaths from influenza in the great towns continued to rise throughout the early part of the year, from 99 in the week ending Jan. 5 to a maximum of 2,183 deaths in the week ending March 2. The epidemic declined slowly, and it was not until the week ending May 11 that fewer than 100 deaths were

Dr. F. J. Russell Stoneham, D.A., has been appointed senior anaesthetist to the Birmingham Accident Hospital and Rehabilitation Centre.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

ANY QUESTIONS?

Dermatitis Herpetiformis

Q.—What is the cause of dermatitis herpetiformis (Duhring's disease) or pemphigus pruriginosus? A man aged 50 has been confined to bed with this condition for the past nine months. Sedative lotions and ointments have been tried with varying success, as have arsenic and iron internally, calcium and adrenaline injections, sulpha drugs, etc. What is the correct treatment?

A.—The aetiology of dermatitis herpetiformis is obscure; focal infection, the absorption of toxic agents from the intestines, a specific virus infection, and—on the slender evidence of the frequently present eosinophilia—an allergic basis have all been suggested at different times. Arsenic given in increasing doses to the limit of tolerance, and then scaled down, in a series of intensive courses, each spread over ten days, is often beneficial and permits of the high dosage essential to obtain a result. Arsenic can also be administered intravenously as neoarsphenamine. Hexamine has proved useful in some cases, and the administration of small doses of sulphapyridine is constantly effective, proving almost a specific therapeutic test. The failure of the sulpha drugs, which may include sulphapyridine, as reported in the question, throws doubt upon the diagnosis, and suggests pemphigus as an alternative. Bayer's "germanin," had it been available, might well be the remedy of choice, although requiring some experience if unfavourable reactions are to be avoided.

Modern Colostomy

Q.—How does a modern colostomy differ from the old-fashioned classical operation?

A.—The chief purpose of a colostomy is to divert the contents of the colon completely from the portion of the bowel below the artificial opening. The colostomy should be made in the most suitable part of the colon, and care should be taken that the opening does not retract within the abdominal wall. In former times sufficient care was not always taken to see that the faecal stream was completely diverted; the rod commonly utilized to form the spur was frequently removed too soon and some of the faeces used to enter the lower part of the bowel. Nowadays great care is taken to ensure the formation of a good spur, either by keeping the rod or rubber tube (which transfixes the mesentery) in its position for two or more weeks, or by completely dividing the bowel. The spur may also be made more prominent by causing oedema of the intervening mesentery by tying a ligature loosely round it.

Left inguinal colostomy used to be done sometimes without sufficient consideration of the position of the growth. It is now quite common to perform transverse colostomy, so that the opening may be well away from a growth in the left side of the colon. The opening through the abdominal wall is made smaller than formerly, so as to lessen the risk of ventral hernia; the risk of stricture at skin level is obviated by excising a small portion of skin at the edges of the wound. Occasionally obstruction of the small intestine has followed the slipping of a loop of gut between the abdominal wall and the coil of colon which has been brought up for the formation of a colostomy; nowadays this is prevented by stitching the parietal peritoneum to the mesentery of the colonic loop, and thus shutting the door of this dangerous opening. When the whole of the bowel below a colostomy has been removed, the main considerations are to see that the part brought out to form the permanent anus has a sufficient blood supply, and is sufficiently long to maintain its position without tension and consequent danger of retraction within the abdomen. Such a terminal colostomy is often made through a small stab incision, which sufficiently ensures the patient against the danger of subsequent ventral hernia.

In a discussion on the management of the permanent colostomy (*Journal*, Aug. 18, 1945, p. 229) the term "modern colostomy" was used strictly with reference to the modern treatment for cancer of the rectum. Mr. A. Lawrence Abel was making the point that almost all cases of cancer of the rectum, no matter how advanced, including

many cases of four years' history and more than four years' duration, are by modern technique found to be operable. The operation he advised was the abdomino-perineal excision of the rectum, which entails removing the whole of the last 18 inches (45 cm.) or so of the large intestine—i.e., from about the middle of the pelvic colon down to and including the anus and perianal tissue. This leaves the cut end of the pelvic colon free to be brought through the abdominal wall, and therefore becomes a terminal colostomy in practically all cases. The term "modern colostomy" was used to emphasize Mr. Abel's view that cancer of the rectum should be excised in all possible cases, even with secondaries in the liver or some actual growth known to be left in inaccessible parts of the pelvis; in this terminal colostomy the wall of the bowel was sutured to the peritoneum and the skin. Very few cases developed any herniation or bulging of the abdominal wall, and there was very little projection from the skin. If every endeavour was made (and Mr. Abel claimed success in over 90% of cases) to remove the actual growth by a one-stage operation, using the pre-operative technique he outlined, a much more satisfactory colostomy was obtained than the old-fashioned classical operation, and it was more easy to control.

Coroners and Mental Hospitals

Q.—Necropsies are carried out as a routine in most mental hospitals. Is it obligatory to supply the coroner with a copy of the post-mortem notes on certified or temporary patients when there is no doubt as to the cause of death? In such a case, can the coroner dictate the extent and scope of the post-mortem examination? Has the coroner a statutory or other right to demand that with every notice of death in the case of a certified or temporary mental patient there should be attached a form, signed by the nearest relative, stating that they are satisfied with the treatment received by the patient and do not desire an inquest? This seems a most undesirable practice, apt to initiate a suspicion that ill treatment is common in mental hospitals.

A.—The coroner's powers and duties are laid down in the Coroners Acts, 1887–1926. When he is informed that the dead body of a person is lying within his jurisdiction, and has reasonable cause to suspect that the person has died a violent or unnatural death or a sudden death of which the cause is unknown, or has died in prison (or in certain other circumstances), he must inquire into the death.

When a certified or temporary patient dies in a mental hospital (etc.) the superintendent must notify the coroner in writing, and give a statement of the facts, before the end of the next day. Now the coroner has no legal power to call for a copy of the post-mortem notes, nor for a form signed by the next-of-kin expressing satisfaction with the treatment. On the other hand, he has the legal power to declare in any case that he is not satisfied with the statement of the facts, and to treat the death as one that puts him on inquiry. Then he may do any or all of the things the Acts say he may—i.e. summon the medical attendant of the deceased to give evidence on the cause of death, and direct him or some other practitioner to make a post-mortem examination and report in writing, and order any special analysis or test to be made. Briefly, the questioner has the choice between doing what the coroner asks, and declining and submitting to having all his deaths inquired into by the coroner's statutory procedure.

Effect of Tobacco on the Heart

Q.—I should like information about (1) symptoms of tobacco poisoning of the heart; (2) differential diagnosis; (3) any recent literature on the subject.

A.—There is still much controversy as to whether tobacco damages the heart at all. The evidence is mainly statistical, indicating a higher proportion of electrocardiographic abnormalities and a lower expectation of life in smokers than in non-smokers. It is probable that in the cardiovascular, as in other systems, tobacco acts by aggravating pre-existent disorders rather than by producing a specific syndrome of intoxication. The only common symptoms are transient acceleration of the pulse and elevation of blood pressure during smoking, a tendency to extrasystoles, and rather more than the normal increase in pulse rate and breathlessness on exertion. In those already suffering from coronary sclerosis smoking may precipitate attacks of angina pectoris. The differential diagnosis is from other conditions which may increase cardiovascular irritability, such as emotional stress, caffeine, etc. There does not appear to be any recent scientific review of the effects of tobacco-smoking on the circulation, but original data and references are given in an article by H. G. Hadley (*Med. Rec.*, 1941, 153, 267).

Boveri Test for Tuberculous Meningitis

Q.—What is known of the Boveri test for tuberculous meningitis? Is this test—bleaching of a solution of potassium permanganate by the cerebrospinal fluid—given only in tuberculous meningitis? On what factor does the bleaching action depend?

A.—Reference to several comprehensive works on clinical pathology yields no information about this test. Admixture of equal volumes of a dilution of human plasma in distilled water, contain-

ing 100 mg. protein per 100 c.c., and of a 1 in 5,000 solution of potassium permanganate completely bleaches the latter, as would be expected. Potassium permanganate liberates oxygen in the presence of any organic material, and is thus decomposed. This is, therefore, no more than a rough test for excess of protein, and would give a positive result in any acute meningitis. If it has been found of the slightest use in the past, it can only have been when facilities for the proper examination of the fluid were not available.

Penicillin for Styes

Q.—How is penicillin used in the treatment of styes?

A.—Penicillin locally gives excellent results in styes. It is best used after epilating the infected lash or lashes and expressing such pus as is present. Penicillin ointment can then be smeared in the first place, on the healthy lid margin to counteract any reinfection. The infected area is then covered with a thicker layer of ointment. This procedure can be repeated four or five times a day, and maintained for two or three days. It is essential that the ointment be made up in a suitable base, as an unsatisfactory base decomposes the drug. It is best to use specially prepared ointment bases, such as those put up by British Drug Houses and by Boots. These are adequately buffered and sterilized. The most suitable concentration of penicillin is 250 to 400 units per gramme. These ointments are more stable than solutions, and remain active for at least a fortnight at room temperature. There is no point in the systemic use of penicillin in styes, for adequate concentrations are obtained by the local application. Though styes can be rapidly brought under control by local penicillin, and reinfection and relapse frequently prevented, it is still essential to recognize that most patients suffering from styes require general treatment to counteract their poor resistance to infection. At school treatment centres it has been found that penicillin by itself does not solve the problem of recurrent styes in children. It is still necessary to provide general constitutional treatment for such children.

Time of Death after Injury

Q.—A necropsy at 8.30 a.m. on the body of a man alleged to have been shot the previous afternoon, revealed an entrance wound in the right abdomen and an exit wound in the left buttock. There were eight punctures of the intestine, the left hip was fractured, and the left external iliac vessels were ruptured. In the peritoneal cavity there were 1½ pints (850 c.c.) of fluid blood with no clots. The climate in this North-West Frontier Province is subtropical, and the maximum temperature at the time was 112° F. with no rain. One medical witness said that death must have taken place not later than half an hour after the shooting. Another medical witness stated that blood clots four to six hours after death in sub-tropical climates, and after twelve hours liquefies again. In his view the man could have lived for more than two hours, and could have made a statement after the injury. Please comment on these two different views.

A.—Any opinion as to the duration of survival, or the possibility of voluntary acts, after penetrating injuries of the abdomen must be very guarded. No definite opinion is warranted from the quantity of blood found or its condition with reference to clotting. Since the bowel was perforated in this case, the admixture of intestinal contents from the ruptured bowel would prevent the normal clotting of blood. Opinion in such cases is best assessed on microscopical examination for signs of repair in the wounds themselves. The infiltration by leucocytes of the periphery of the wound starts in about one hour, and by the extent of the leucocytic migration and subsequent stages of repair, which follow in regular sequence, a more definite opinion can be formed. In this particular case one can see no reason why the person should not have lived and have given a coherent statement two hours after the injury.

Painful Feet

Q.—A patient has been suffering for several months from swelling and marked tenderness of the pressure points of the soles and undersurfaces of the toes of both feet. There are thickening of these areas and a dusky flush. Padding the arches with adhesive felt to relieve the strain on the other parts of the soles relieves the pain for a day or two, but very soon these areas also become painful. In the past 18 years I have seen about six similar cases. They seem ultimately to clear up, but take a matter of months or years to do so. Is there any effective ambulatory treatment?

A.—The causes of pain in the pressure areas of the soles of the feet are so numerous that it is not always possible to give a dogmatic opinion even when a case is seen personally. Still less is a correspondence answer likely to hit the mark. However, in the absence of any recognizable local lesion, the following suggestions may help. The earliest stages of ischaemic conditions, whether arteriosclerotic, thrombo-angitic, or spastic, often cause pain, redness, and some swelling, before other effects become obvious. Elderly patients in whom the subcutaneous fat is undergoing atrophy and absorption all over the body, including the soles of the feet, not infrequently complain of tenderness over pressure areas, and upon examination the bones can be easily palpated through the thinned coverings. Diabetics,

short of obvious clinical signs of neuritis or arteriosclerosis, may complain of such symptoms, sometimes associated with a little swelling and dusky redness. A further condition, which is becoming so rare that it may easily be overlooked, is gout. The deposit of biurate crystals in the fibro-fatty pads of the heel and ball of the toes may be so great as to cause recognizable nodules, but in lesser cases the manifestations are not unlike those described in the question. A patient who has been off his feet for a long time on account of illness, or who has suffered from a wasting disease, may complain when he first starts to get about again. Like the elderly patients, there is here loss of resilience in the pads of the sole. Finally, in these days when so much is attributed to vitamin shortage it is just necessary to add that quite rarely shortage of the B factors may be the cause of pain and swelling in the soles of the feet. In this answer, which is by no means exhaustive, it is of course assumed that there is no evidence of gross general or nervous disease.

So far as treatment goes, if one of the above causes is discovered it must be dealt with. Local treatment by skilful padding is correct, but sponge rubber might prove a more suitable material than felt in a case of this type, where relief from pain rather than correction of a deformity is the aim.

Penicillin for Gonorrhoea

Q.—Is instillation of penicillin solutions into the urethra of value in the treatment of acute gonorrhoea? If this worked it might be less painful than repeated intramuscular injections.

A.—Instillations of penicillin solutions into the urethra have been tried in gonorrhoea, they are of some value—as are solutions of sulphonamides—but are far less effective than penicillin parenterally, and cannot be relied on to effect cure of the condition. Now that gonorrhoea can usually be cured by a single injection of penicillin suspended in beeswax-plant oil the question of pain assumes much less importance.

Alveolar Absorption

Q.—I recently had toothache and x rays showed two molars which had been filled, with "bony absorption at the alveolar margin". The teeth and roots appeared sound radiologically, and externally the teeth seemed sound, there was no sign of inflammation of the gums. It has been suggested that this is "ano domini" (I am 46), it at there is no treatment, and that when the pain becomes unbearable I must have the teeth extracted. What is the cause of the alveolar absorption, and is there no treatment?

A.—As the teeth in question appeared sound on both clinical and x-ray examination, it can be assumed that the toothache was not caused by any carious cavity. As they had been filled previously, it is possible that the pain was due to a hyperaemic condition of the pulp, or even an acute pulpitis. The bony absorption at the alveolar margin, however, means that there is some degree of pyorrhoea present, with the subsequent exposure of the cementum or dentine of the root. Extremes of temperature, or the contact of some jam or syrup with this area, would cause pain. The treatment of pyorrhoea cannot be entered into here, except to point out that it depends on the surgical elimination of all pockets and the keratinization of the gum margin by constant friction with the toothbrush and wooden tooth pick. The exposed dentine can be treated with silver nitrate, or, if the pain is acute, by the application of zinc oxide and clove oil.

Pregnancy in Middle Age

Q.—I have recently been asked the same question by three patients—ladies of 51. "Although menses are still fairly regular, can I safely give up contraceptive methods, or is there still a risk of pregnancy?" All these ladies are married with children, and in no case has there been a pregnancy for 19 years.

A.—Fertility in woman is at its peak between the ages of 20 and 24, declines rather slowly until the age of 35, and thereafter falls rapidly until it approaches zero at the age of 45 to 50. It is, however, impossible to say at what age sterility is absolute. So long as menstruation continues there is a slight chance of pregnancy, and conception can occur even after the menopause. This is because ovulation sometimes continues, regularly or irregularly, in the absence of menstruation. The long period of sterility (presumably voluntary) in each of these cases does not preclude conception, although it may mean that it is a little less likely. It is perhaps relevant to comment that the husbands should not be excluded from consideration—a low degree of fertility in the male might to some extent counteract lowered fertility in the female. Probably the best plan is to explain to each patient that, although the chances of conception are remote, they nevertheless exist and will continue to do so for at least one or two years after the menopause. Thereafter, although pregnancy is still not impossible, it is so unlikely as to be unworthy of practical consideration. It is then up to each patient to decide whether she is willing to take what amounts to the slight risk involved in abandoning contraception at the present time.

Some published cases of post-menopausal pregnancy, and the question of contraception and the menopause, were referred to in answers published in the *Journal* (Dec. 11, 1943, p. 771, and

June 30, 1945, p. 933). These might be consulted. According to the Registrar-General's Statistical Review for England and Wales for 1940, 24,793 "maternities" were credited to women aged 40-44, 2,203 to women aged 45-49, and 18 to women of 50 and over. We do not know, however, whether these women had ceased menstruating or not. About 0.3% of births in England and Wales, Scotland, Australia, and New Zealand are in women aged 45 and over.

Flatulence and Auricular Fibrillation

Q.—At the age of 75 I have auricular fibrillation and at night I suffer from flatulence, lasting one to two hours and relieved often by a mixture of alkalis. When walking, say 20 to 50 yards (18 to 45 m.), I get flatulence, and have to stop for one or two minutes. I very seldom have anginal pains. Can you explain the correlation between flatulence and the cardiac condition?

A.—Flatulence is a common symptom in disorders of the heart. This is specially true of syndromes due to deficiency in the coronary supply, such as coronary thrombosis. In general, patients are unable to distinguish sternal oppression from true dyspeptic symptoms; what is taken to be flatulence often leads to attempts to eructate, which aggravates the symptoms. Flatulence related to exertion is probably of coronary origin and is the counterpart of anginal pain; this symptom should, therefore, be treated by preparations designed to relax coronary spasm and promote the coronary circulation. In the present case the occasional anginal pains indicate that there is at least a coronary element in the whole syndrome. It is suggested that this patient should take tab. trinitrin, gr. 1/100 (0.65 mg.), allowing it to dissolve under the tongue a few minutes before starting walking. If it is effective in preventing the onset of flatulence on exertion, it might be taken six or more times daily in the same manner. For the prevention of nocturnal flatulence, trinitrin might be tried on retiring, or, alternatively, a simple mixture of chloral hydrate with bromide, gr. 10 (0.65 g.) of each. Trinitrin might be employed also for the relief of nocturnal attacks. Should these methods fail to relieve the flatulence some carminative may be given, such as peppermint water 3ss (14 c.cm.); if sodium bicarbonate gr. 30 (2 g.) is added to this, gas is produced in the stomach; this evokes the desire to belch, and once the gas is expelled from the stomach the sensation of flatulence is likely to disappear.

INCOME TAX

Travelling Expenses and Cost of Shelter

C. P. asks can a claim be made for (a) the cost of visiting an infant welfare centre 20 miles from home, and (b) the use from time to time for professional purposes of an air-raid shelter which cost over £100.

. (a) If, as would seem to be the case, the work at the Centre is carried out as a separate appointment unconnected with the general practice of C. P.'s husband, the answer is "No." (b) No part of the cost of the shelter can be claimed, as that ranks as capital outlay and not as a current expense. So far as annual expenses are concerned the rule with regard to the use of premises for professional purposes is that a proportion of the annual value as assessed to income tax can be allowed. But if, as is assumed, no increase was made in the assessment of the main premises because of the erection of the shelter, C. P. cannot establish that any tax is being paid on the annual value of the shelter and no claim would be competent.

Appointment: Travelling Expenses

H. S. is in practice and sees patients at his residence and elsewhere. He also acts as chairman of a Medical Recruiting Board and incurs expense in travelling from his residence to the place of meeting. Can he claim these expenses as a deduction?

. The expense is not deductible under Schedule E, and the only way in which H. S. appears able to obtain any relief in respect of the cost of travelling is for the remuneration in question to be included in his general earnings for assessment under Schedule D and not assessed separately under Schedule E. Whether the authorities will consent to that arrangement we cannot say, but H. S. may be advised to make such a request through the local inspector of taxes.

Cost of Fitting Out Laboratory

F. H. S. has spent between £50 and £100 on fitting out a laboratory for research work from which he gets no financial return. Can he recover tax on this amount?

. No. In the first place the expenditure is in the nature of capital outlay, and, in the second place, as no financial return is expected the expenditure was not "money wholly and exclusively laid out for the purposes of the profession" in the sense in which those words would probably be construed by the court.

LETTERS, NOTES, ETC.

Surface-marking the Lower Border of the Liver

Mr. L. R. C. AGNEW (Glasgow) writes: In his letter (Dec. 29, p. 941) Capt. R. P. Gillespie mentioned an auscultatory method, new to him, for defining the lower border of the liver. It may be of interest to note that a similar method, so-called "auscultatory percussion," has been used for defining cardiac surface-markings. The stethoscope chest-piece is placed on the sternum just proximal to the xiphoid process. A forefinger is now made to scratch the skin surface from the posterior axillary line to the relevant border of the heart. A sudden increase in intensity and clarity of the hitherto muffled sound of scratching proclaims that the cardiac border has been reached. Repetition of this process from varying points on the thoracic skin enables the entire area of cardiac dullness to be ascertained. Similarly, by vertically scratching the right side of the abdomen the liver border may also be mapped out. Capt. Gillespie seems correct in his surmise that this method for surface-marking the liver finds no place in clinical teaching. I am within six months of the Final M.B. examination and have never heard of it in lectures or seen it mentioned in current British textbooks. Auscultatory percussion of the heart is, however, mentioned in Major's *Physical Diagnosis* (1944, p. 198) and other American works. In obese subjects especially I have found the test of value, both for heart and liver surface anatomy, but have usually used it to confirm clinical findings based on the traditional methods of palpation, percussion, and auscultation.

Surg. Lieut. M. B. CARSON, R.N.V.R. (Stevnage), writes: With reference to his letter dealing with the surface-marking of the lower border of the liver, Capt. R. P. Gillespie is mistaken in supposing that the method he describes indicates the lower hepatic margin. The "loud rubbing noise" is only obtained while the stroking finger is passing over the region of the stomach and ceases when the limits of that organ are reached. This method was taught me as a student as a rapid means of obtaining a rough idea of the size of the stomach, and, so far as I am aware, is not of Russian or Polish origin.

Dr. HILDA M. DENHOLM-YOUNG (Farningham, Kent) writes: With reference to Capt. R. P. Gillespie's letter, the auscultatory method is not the monopoly of Russians and Poles, for it has been taught in Edinburgh for at least 16 years.

. And in a certain well-known London hospital the method was taught at least 20 years ago.—Ed., B.M.J.

Venereology

Lieut.-Col. HENRY RICHARDS, R.A.M.C., writes from the M.E.F.: Due to the mail's delays a copy of the *Journal* for Oct. 20, 1945, reached me yesterday. I cannot agree with Brig. T. E. Osmond (p. 556) that the term "venereologist" has supplanted "dermatologist." We yet have specialists in dermatology in the Services, and the Dermatological Section of the Royal Society of Medicine still flourishes. The ophthalmologist and the laryngologist instanced by Brig. Osmond do make a study of the eye and the larynx respectively. The specialist in venereal diseases does not necessarily make a study of venery. This is my objection to the term "venereologist." Nor do I agree that by being destructive my criticism is thereby valueless. If my car is not running well it is my job to point this out, but I call on an expert to diagnose and remedy the defect. My letter drew attention to what I regard as a defect in medical terminology. That it was not altogether without value is proved by the erudite, if light-hearted, intervention of Dr. Robert Cook (Nov. 3, p. 634).

R.A.M.C.T.A. Reunions

Lieut.-Col. J. N. GROVES, D.S.O., R.A.M.C., writes from 11 Charmouth Road, St. Albans, Herts: Will all old T.A. R.A.M.C. officers please note that there is a social evening on the first Friday of every month at 7 p.m. at the Central Mess of the Duke of York's Headquarters, Chelsea. The 140 County of London Field Ambulance have already formed an Old Comrades Association for all pre-war and wartime members. It is desired to make this a general meeting place of all officers and other ranks of 140 Field Ambulance, 13th London G.H. 141 Field Ambulance, the 8th Field Hygiene Section and any affiliated units. Many old faces were there on Jan. 4.

Obstetric Instruments Wanted

Dr. STEFFAN LASKI, of the Polish Forces, Camis Esquin Camp Helensburgh, nr. Glasgow, writes: Forgive me please my asking you to help me to get an obstetric instrument set. The condition in Poland require to do the obstetric operations in patients' lodgings; because of the war I lost my set in Poland and all my effort to get another set in Great Britain were unsuccessful. The shopkeepers answer it is impossible to get now even a new midwife forceps, so I intended to ask you kindly to help me to buy a set I can pay any reasonable price. Can any reader help?

BRITISH MEDICAL JOURNAL

LONDON SATURDAY JANUARY 26 1946

SOCIAL MEDICINE*

By

MAJOR GREENWOOD, D.Sc., F.R.C.P., F.R.S.

Professor Emeritus of Epidemiology and Vital Statistics in the University of London

A professional statistician is, if a sexagenarian, a cautious prophet; but I do not risk much in prophesying that a majority of you will become general practitioners, *doctors*, that is why I have taken for my subject what we call Social Medicine and the Germans call Social Hygiene. What Prof. John Ryle (1943), now at Oxford, means by Social Medicine is precisely what the late Prof. Alfred Grotjahn (1923, 1932) of Berlin meant by Social Hygiene—viz., the effects, good and bad, on the health of human beings of their nature and nurture, *all* their nature and nurture, not some items of it. We reject the word "hygiene" because—whether logically or not—to English men and women hygiene does always suggest either the statutory duties of a medical officer of health or, on a lower plane—and, after all, we are not always on mountains—various useful objects of commerce, for some of which we have to queue, filters and other things. Grotjahn rejected the word "medicine" because in German professional circles social medicine suggested sometimes what we call professional ethics and, oftener, the technical and administrative problems of health insurance. I do not think I need enlarge upon the obvious—namely, spin sentences expounding the truism that doctors, who are trying to help human creatures, cannot succeed unless they are interested in people. That is obvious.

There is a story, so old that it may be new to some of you, of Thomas Sydenham, when asked by a pupil what books he should read, replying, "Read *Don Quixote*—it is a very good book; I read it still." Learned men have discussed what he meant by that. Dr. Johnson actually said:

"The perverseness of mankind makes it often mischievous in men of eminence to give way to merriment. The idle and the illiterate will long shelter themselves under this foolish apophthegm."

With apologies to the formidable shade of Samuel Johnson, I suggest that it was not Sydenham who was talking foolishly. Two hundred years later a wise physician whose name you will now before you sit your finals, H. G. Sutton, said in the preface to a course of lectures on Medical Pathology (I must trust to memory, for I have no copy): "You will see I often quote Shakespeare; he understood human nature." Sydenham had the same opinion of Cervantes. This is obvious but not very helpful. Granted that the good doctor must understand human beings, how is one to compass understanding? Reading Cervantes and Shakespeare is not enough. I think we may learn something from the successes and failures of the apostles of Social Medicine; that is why I am going to take some of your time in telling the story of an apostle whose name is almost certainly unknown to you and whose voluminous works you are unlikely ever to read—Alfred Grotjahn (1869–1931), the first and, for all I know, last Professor of Social Hygiene in the University of Berlin.

Alfred Grotjahn's father was a busy country doctor, and his on was "up against it" from the beginning. Seventy years go the enuresis nocturna of nervous children was treated, even in a doctor's family, drastically—with flogging, confinement to the cellar, and the throwing of pails of cold water over the patient's naked body, memories of which recurred in dreams when he was a sexagenarian. The curriculum of a classical

Gymnasium (Grotjahn's account of which suggests an exaggerated parody of a British public school a hundred years ago—not the intellectual paradise which Matthew Arnold described) was thoroughly uncongenial, and its vicium remained at school until he was 21, when he succeeded in passing the arbitrary examination; and, as he tells us, he acquired in all these years of study no real knowledge of the classical or any other foreign languages, or of mathematics. He never did master any foreign languages; he could in later life read English and French fairly well (*leidlich*), but neither speak them nor understand them when spoken.

By the time he had attained the comparative freedom of a medical student Alfred Grotjahn knew a good deal about human suffering and frustration from personal experience, not being a merely selfish introvert, but a big if not great man, it led him to feel for others and set about helping them. He became a socialist and attended academic lectures on economic. In England in the early eighteen-nineties a diligent medical student could qualify in four years. Grotjahn took six, and in 1896, at the age of 27, set up in general practice in Berlin. He earned his living as a general practitioner for more than twenty years but already, in 1896, his ambition was to devote himself to social medicine and he published the first of his many books in 1898. It was a treatise on the social pathology of alcoholism, and he gradually attracted attention in academic circles. The then famous economist Gustav Schmoller, whose pupil he became and of whom he speaks with affectionate reverence in the autobiography part of which I am summarizing, thought well of him and tried to obtain his habilitation. The first attempt was unsuccessful, Grotjahn, like most psychological left-handers, inspired both affection and dislike, the famous Rubner was not one of his admirers, and Rubner was very powerful, but at last, in 1912, Grotjahn was habilitated as titular professor of social hygiene with a trifling salary and a couple of rooms on the top floor of the University Institute of Hygiene. He was now a man of 43, author of many books and papers, editor of a *Zeitschrift*, and still earning his living in general medical practice. After the war, in 1920, he became a full professor with a, theoretically, adequate salary. For three years, 1921–4, he combined his academic duties with those of membership of the Reichstag, found them, of course, hopelessly incompatible, and for the last seven years of his life devoted himself wholly to social medicine. This bald summary cannot bring home to you the intense activity of Grotjahn's life, his scientific literary output was great, but in addition he was an active promoter of social reforms and took pains to acquire the technique of committee work, parliamentary drafting, and much besides. In journals he would be called an eminent publicist and an eminent scientist. Also, he was a busy doctor. I will add—whether it will move your pity or your admiration I do not know—he did not smoke, drink neither alcohol nor coffee, ate no flesh food, and never permitted anybody to clean his boots, dust his books, or render him any personal service.

The easiest way to understand the strength and perhaps the weakness of Grotjahn's concept of social hygiene—our social medicine—is to read his textbook, *Soziale Pathologie* (third edition, Berlin, 1923): a sample would be his account of the social pathology of tuberculosis. In the most popular textbook

* A paper read to the Cambridge University Medical Society on

social pathology of tuberculosis was not overlooked. In the eighth edition (this was a decade later than the edition of my undergraduate days, but not, I think, fundamentally altered) one has a statistical paragraph in which "improved social condition of the people, better housing, better food, better habits" are regarded as the most important factors of a declining death rate. Nearly two pages are given to environmental and hereditary influences: "Exposure to dust, close confinement, long irregular hours and low rates of wages favour the prevalence of the disease." The popular medical textbooks of this generation—at least those I have examined—say no more, indeed rather less. Grotjahn's chapter on tuberculosis is a systematic expansion of such hints. The relation between poverty, housing, and occupation on the one hand, and higher or lower mortality from tuberculosis on the other, is illustrated on (mainly German) statistics.

We find an account of the cost, not only in mortality but also in days of sickness, for which purpose German data are peculiarly valuable because of the longer history of State health insurance in Germany. Even now, after a generation of State health insurance, there is no generally available British analysis of morbidity in occupations so good as was published in Germany with respect to the Leipzig area more than a generation ago.

Grotjahn did not let his readers lose sight of the interaction of social-economic factors, and was one of the first medical teachers to stress the folly of supposing that sanatorium treatment alone could be a panacea for a social evil.

To advocate the segregation of patients with open tuberculosis without having made adequate provision for their dependants during the treatment and for the patient's employment after "cure" is just as fatuous as the advice of the mythical physician to a phthisical charwoman that she should winter in the Riviera. To young people in 1945 this is obvious; many clever people, young and old, did not see it 30 years ago. The problem of communal health, like that of peace, is indivisible. Grotjahn was a stimulating teacher who did see the problem of social medicine as a whole. Like other men, great or small, he had weaknesses, and, as it is much easier to copy the faults of a great man than to acquire his virtues, it is not ungenerous to inquire what they were.

I have mentioned that Grotjahn obtained academic recognition very slowly. No doubt this was partly due to political heterodoxy, partly to academic trade-unionism—the professional academic sometimes resents the intrusion of amateurs—but there may have been less petty motives. Both in his *Soziale Pathologie* and in his autobiography Grotjahn speaks of the importance of medical statistics:

"Without being myself a statistician or, through lack of the indispensable mathematical ability, being able to become one, I was, from the beginning, convinced that medical statistics must be regarded as the basis of social-pathological and social-hygienic study and therefore needed the most careful cultivation. At that time the victorious march of bacteriology had relegated medical statistics to the background. In hygienic circles then it was quite generally believed that the nature of great epidemics could be sufficiently explained on purely bacteriological lines. It was not necessary to rob bacteriology of a single leaf of her garland in order to have to reckon with strong distaste in medical circles if one, as I did, in season and out of season, insisted that this view was erroneous and that a quantitative study of the theory of epidemics was as indispensable as before the bacteriological era. Since then this view has made its own way, and now medical statistics have the hope of attracting more general interest. Unfortunately, my high appreciation of statistics has never led me to do any really scientific work in their field, for I lacked the indispensable minimum of mathematical ability"—*Erlebtes und Erstrebtes*, p. 128.

In this passage there is some self-deception. It is true that no one without a natural gift for mathematical reasoning and thorough mathematical training is likely to make a first-rate contribution to the theory of statistical technique, but any man of common ability can, if he gives himself time, acquire a competent knowledge of modern vital-statistical methods, and Grotjahn was a man of more than common ability. Grotjahn would not give himself time, and persuaded himself that he could do without the knowledge.

He could do this easily because he was much more interested in studying people than in reading about them. Speaking of

the tours organized by the Health Committee of the League of Nations, he wrote:

"I took every opportunity of leaving the official hygienic caravan to take an uncondemned stroll through the working-class district of the town we were visiting. Observations made in this way tell one more about the real hygienic level of a population than the inspection of selected hospitals and institutions made to look pretty beforehand. One must watch the little children in the streets and courts of the poor districts, look at school-children as they enter and leave the school buildings with an eye to their state of health, stroll attentively through the courts and alleys, have an eye on the country folk coming to market and assess their physical quality. I am accustomed never to enter or leave a railway station outside Berlin without spending a few minutes in the waiting-rooms of lower railway classes and looking at the people there. Ten minutes in the third-class waiting-room at Copenhagen and ten minutes in the corresponding place at Belgrade give one a better idea of the differences in cultural levels within this little Europe than thick books. Anybody who has given his attention to this can soon, make instructive comparisons, and receive impressions not to be had from reports, descriptions, and statistical tables."—*Erlebtes und Erstrebtes*, p. 266.

A principal interest of my life for over forty years has been the study of medical statistical tables; that, however, does not prevent me from saying that what I have just quoted is profoundly true and adding that no one should be a doctor at all who is not, like Grotjahn, more interested in human beings than statistical tables, laboratory experiments, or even the science of medicine. Nobody without an interest in living people, just as people, will add much to social medicine. But although the chariot of the soul cannot move at all without the horses of emotion, it may come to grief if the charioteer—reason—cannot guide the horses. One may misinterpret what one sees in the third-class waiting-room. Sometimes Grotjahn was mistaken. Here is a trivial but instructive example.

Grotjahn, like many social reformers, distrusted prophylactics generally advocated by any majority, medical or lay. There are two reasons for this bias. Pioneers are in a minority and apt to assume that what is generally believed is false; they also fear that if the public think disease can be prevented by so relatively cheap a method as inoculation the public will not insist on more fundamental and costly reforms. It is much cheaper in money to vaccinate a slum population than to rehouse them. So Grotjahn was suspicious of orthodox arguments in support of vaccination against smallpox, particularly of deductions from the experience of the German Army. He used counter-arguments similar to those of Creighton—that the severity of the disease varied, that it had declined in countries where vaccination was not compulsory, etc.—and remarked that in modern times the accuracy of the records was greater than in the past, when cases of measles, scarlet fever, and chicken-pox may have been included in the statistics. So far so good, but he added to his criticism this footnote:

"In 24 of the States of North America with 64 million inhabitants, in the first six months of 1921, 18,374 cases of smallpox were notified without a single death, and in the previous period 16,311 with one fatal case were notified. This fatality of 1 in 34,000 is only intelligible if one supposes that not all the cases were of genuine smallpox—at any rate, that chicken-pox was included. If such smallpox statistics are published and reported on in 1922, how many cases of illness may have been incorrectly included in earlier times?"—*Soziale Pathologie*, p. 25.

Quite apart from the fact that in earlier times the fatality of smallpox, as recorded, was high, this criticism of the American statistics (which could equally have been applied to our own) wholly ignores one of the most interesting epidemiological events of our own time—viz., the emergence of a variety of smallpox, sometimes called alastrim, in which the physical signs of severe "classical" smallpox were widespread but the patients did not die. It is now well known, through the flocculation test (see Craigie and Tulloch, 1931), that dermal material from patients gave positive reactions whether the clinical disease were "classical" smallpox or alastrim, but varicella crusts did not. In other words, Grotjahn's condemnation of the American statistics was ill founded. He had not himself had any practical experience of the variant which has a local interest for Cambridge men (Copeman, 1920), and his knowledge of epidemiological literature was not deep.

I do not pause upon these petty weaknesses of a faithful servant of humanity to depreciate him but to warn ourselves.

To the *Forscher* of a German university a generation ago, to a man like Rubner, Grotjahn would have seemed no *Forscher* at all, but, in our jargonese, a publicist, using the researches of others, not himself making discoveries, and speaking contemptuously of techniques he had not mastered. An unjust and incomplete statement indeed, but not without a tiny kernel of truth. If we came to think of social medicine as wholly a matter of feeling and intuition, came to speak contemptuously of "mere" laboratory science, of "mere" technique, we should fail. The rejoinder of the "mere" technician is crushing. He does understand his technique, he does make discoveries; do you? If our hopes for the future are even partly realized doctors will not be so isolated as they have been: they will have opportunities of pooling their experience at a lower level than, say, the General Register Office.

Just as most people at some time in their lives have started to keep diaries, many doctors have begun to keep case books and records. Few diarists continue for years, and perhaps not many doctors persevere. There are excellent reasons: one grows busy and has no clerical help. That is where *real* health centres are important. Those who would like to do medical-statistical or social research are deterred by the thought that their experience is limited: while Government "experts" have hundreds of thousands of data, they only have tens or hundreds. The fear is groundless. Paucity of data is partly compensated by the intimate knowledge of him to whom these data are records, reminders, of living human creatures he has known intimately. The paucity itself will be compensated, the tens and hundreds of records become thousands if doctors work together; the group must not, however, be so large that intimate knowledge of the material is lost. The doctors must work up their own material. Of course, I do not mean that a doctor must not seek technical advice: it would be silly to rush to the opposite extreme and proclaim that his intimate knowledge of the facts puts him above the reach of those vagaries of chance which "mere" statisticians emphasize. The doctor who makes neither too little nor too much of technique is the salt of the earth. It is futile to assign an order of precedence in scientific merit—like debating who was the greatest poet in history. But if I had to choose the best contribution to statistical epidemiology made in England during the last ten years I should pass over the officials and professors and cite *Epidemiology in Country Practice*, by Dr. W. N. Pickles (1939), a country doctor. Dr. Pickles knew and cared for the people the records of whom were his statistics. He made discoveries which eluded officials and professors whose material was just cards.

It is a very long time since research on that level has been done by town doctors. This is a model for research in social medicine.

A novelist who wrote a "best seller" fifty years ago, Miss Beatrice Harraden, has a pretty fable of a traveller in quest of the Ideal, the temple of which, he believed, was to be found on the summit of an almost unscalable mountain. After years of toil he discovered that the temple was not there at all, but down in the place from which he came—a building in which he had played as a child. You, I am sure, whose most impressionable years have been lived in this noble seat of higher learning and research, have been thrilled by the thought, the aspiration, that you too might be research workers. Do not forget there is a research laboratory greater even than the Cavendish: the streets, the homes, the factories in which common people pass their lives. There is the laboratory of him who adds to our knowledge of social medicine. Great discoveries are waiting to be made by doctors who, in the words of the Book of Common Prayer, are in love and charity with their neighbours and intend to lead a new life, if by that one may mean intend to master those tools of social research of which statistics—real statistics—and psychology are not the only ones but among the most important.

IRREGULAR HAEMAGGLUTININS AFTER TRANSFUSION

BY

SHEILA T. CALLENDER, M.D., M.R.C.P.

AND

Z. V. PAYKOC, M.D.

(From the Nuffield Department of Clinical Medicine, Oxford)

The development of irregular haemagglutinins, both as a result of iso-immunization in pregnancy and after repeated blood transfusions, is now well recognized, the familiar example being the immunization of the Rh-negative patient to an Rh-positive foetus or Rh-positive transfusion. During the past year, in an attempt to detect and identify such irregular agglutinins, we have made a systematic study of 100 patients receiving transfusions.

The Investigation

The majority of the patients were routine admissions to the medical wards, but as one of the wards is associated with a research department a relatively high proportion of them suffered from blood diseases requiring repeated transfusions. Seven patients from non-medical wards were also investigated, either because they had shown a transfusion reaction or because they were known to be Rh-negative. In all there were 37 cases of haematemesis, 14 of ulcerative colitis, 31 blood dyscrasias, 7 of which were cases of aplastic anaemia; 4 were healthy volunteers who were being bled and transfused for red cell survival experiments. The remaining 14 suffered from various conditions such as battle injuries, sepsis, and menorrhagia. There were 52 women and 48 men in the series.

Methods.—The patients' ABO group and Rh group were determined, if possible before transfusion. The results of Rh grouping after transfusions were uncertain, owing to admixture with transfused cells. This was particularly so in the patients with aplastic anaemia, who were existing practically entirely on transfused blood. Samples of the donor cells were also typed for Rh in most instances. Each patient was questioned

FIG. 1.—Distribution of 958 pints (544 l.) of blood in the series of 100 patients.

about previous transfusions, and an obstetrical history was taken from the women. A note was made of any reaction to transfusion. Samples of blood were taken 10 to 14 days after transfusion, allowed to clot at 37° C., and the serum separated. Each serum was set up in serial dilutions against the patients' own cells and a panel of cells of known ABO, M, N, P, and Rh types. By including always examples of Rh, (CD₅), Rh, (cDE), and rh (cde) it is possible to cover all the six Rh antigens included in Fisher's scheme (Race, 1944). As A, individuals may occasionally develop a, in response to transfusion with A, cells (Wiener, 1941) we included A, cells in the panel in dealing with Group A patients. The investigations were made at 37° C., room temperature, and 4° C. The serum of any patient who had shown a reaction to transfusion or an inadequate rise of haemoglobin was, if possible, re-examined at a later date. Serum from other patients—e.g., those suffering from aplastic anaemia—was examined on several occasions in association with the repeated transfusions. The 100 patients between them received the equivalent of a total of 958 pints (544 l.) of

blood (including transfusions in the past), of which 609 pints (346 l.) were given during the period of the present observations. Most of the transfused blood was in the form of packed cells, the plasma being removed just before transfusion. The amounts received by each patient in equivalent pints of blood are indicated in Fig. 1.

Blood Groups.—Except in 11 cases where red blood cell survival experiments were carried out by giving Group O blood to Group A or B patients, the blood used was all of homologous ABO group. In accordance with the usual practice, however, no attempt was made to secure blood of the same Rh type. Seventeen patients were Rh-negative; these all received some Rh-positive blood. Fifty-eight of the remainder were grouped before transfusion and were Rh-positive; a proportion of these received Rh-negative blood. The other 25 were not grouped until after transfusion, but appeared to be positive. Apart from two patients from non-medical wards, who were included because they were known to be Rh-negative, the material was unselected with regard to Rh types. Discounting these two, 15 out of 98 were Rh-negative, which is the expected number, and the likelihood of errors in grouping having been made after transfusion is therefore not great.

Obstetrical History.—Of the 52 women 12 had had one or more stillbirths, miscarriages, or neonatal deaths, but only one had a history really suggestive of associated haemolytic disease—viz., first infant dead of jaundice at 16 days, 23 years before, then three normal children, then a miscarriage, and finally a child dead with anaemia at 14 days, 11 years before. She was Group B Rh-positive and had a mild transfusion reaction, but no antibody could be demonstrated in her serum.

Reactions.—Thirty-nine of the patients had a reaction with one or more of their transfusions or had a history of reaction in the past. Six of these were Rh-negative—i.e., Rh-negatives were not unduly frequent among the patients showing reactions. It is difficult to get an accurate record of the reaction rate in relation to the number of pints of blood, for where large transfusions have been given reactions may have been due to more than one of the donors used. So far as could be ascertained, however, there were 39 reactions in the 609 pints (346 l.) given during the period of observation, and 90 reactions in the total of 958 pints (544 l.) (Table I). The 90 include 29 in one patient (Case III, below). This same patient had only three reactions during the recent period, and she is largely responsible for the higher reaction rate in the total number of 958.

TABLE I.—Reactions in Relation to 958 Pints of Blood

Type of Reaction	No.
Slight rigor or rise of temperature	68
Severe rigors	5
Jaundice alone	3
Jaundice + some other signs of reaction (e.g., rigor or fever) ..	4
Jaundice + haemoglobinuria	1
Labial herpes	3
Diarrhoea	3
Urticaria	3

Results.—One might have expected to find irregular agglutinins in several of these patients, judging both from the frequency of reactions and from the very large number of transfusions received by some. Such agglutinins were, however, demonstrable in only two cases.

Case I

Mrs. M. S., aged 35. Inactive rheumatic carditis, severe hypochromic anaemia, and menorrhagia. No pregnancies. Group O Rh-negative (rh⁻). Transfused with 1 pint (568 c.cm.) of Group O blood, later shown to be Rh-positive (Rh,Rh₁). No reaction at the time of transfusion, but a rise of temperature to 102° F. the next day. Two weeks later no irregular agglutinin could be found, but on re-examination for hysterectomy six weeks after transfusion the transfusion officer (Dr. W. Ormerod) reported difficulty in cross-matching more blood. A strong anti-Rh agglutinin of the anti-Rh₁ (Δ + Γ Fisher) was subsequently identified in the serum.

Case II

Some details of this case have already been reported (Callender *et al.*, 1945). Miss F. M., aged 25. ? Lupus erythematosus diffusus. Has never been pregnant. Her illness is characterized by recurrent pyrexia, transient rashes, arthritis, and persistent anaemia, for which she has received nine transfusions from eight donors over a period

of a year. Her own group being O Rh-positive (Rh,Rh₁), she has developed four different irregular agglutinins: St (γ Fisher) reacting with all Rh-negative and Rh₁ bloods, and three new antibodies which we have called "anti-Lutheran," "anti-Willis," and "anti-Levy." None of these was naturally occurring, and they are active at 37° C.

The St (γ) was responsible for two transfusion reactions—namely, jaundice, appearing 6 days after transfusion of 2 pints (1.14 l.), both subsequently shown to be Rh-negative, and at a later date a severe haemolytic reaction with haemoglobinuria and jaundice. This reaction was due to blood which was identified later as Rh₁rh. "Anti-Lutheran" was initiated by the blood of one of the two Rh-negative donors, and it therefore may have been partly responsible for the first reaction. "Anti-Willis" was associated with two febrile reactions accompanied by a rigor, but the blood which stimulated "anti-Levy" gave no apparent reaction.

The following notes are included as a contrast to Cases I and II.

Case III

Miss O. T., aged 62. Chronic aplastic anaemia, myelosclerosis. Group O, Rh group undeterminable. First became anaemic in 1937. Between Oct., 1937, and Jan., 1938, received 10 transfusions. History of reaction with all of these. June, 1939, six transfusions—again reactions consisting of rigors and vomiting. First admitted to the Radcliffe Infirmary, Oxford, April, 1940. Twenty-four subsequent admissions up to May, 1945. During this time she has received transfusions on 33 occasions, being given 167 bottles of blood, mostly in the form of packed cells. From April, 1940, to May, 1944, she showed some form of reaction every time she was transfused. On four out of seven occasions since then she has had no reactions. In spite of reactions she has always shown an adequate rise of haemoglobin after transfusion. In 1942 difficulty was once found in cross-matching blood, slight microscopical agglutination occurring with all the Group O donors tested. This difficulty has not recurred, and repeated examinations for irregular agglutinins have been negative.

TABLE II.—Reactions in Case III; April, 1940, to May, 1945

	Type of Reaction	No.
Vomiting +	Slight febrile reaction	8
	Rigor	13
	Severe rigor with high fever	3
	Labial herpes	2
	Urticaria	1
	Diarrhoea	2

Cold Agglutinins.—We did not find any irregular agglutinins which were more active at temperatures below 37° C., but when looking for such antibodies we thought it worth while to record

FIG. 2.—Titre of cold agglutinins in the sera of 95 patients

our findings in relation to the ordinary cold agglutinins. Cold agglutination was examined for microscopically, sediment being removed with as little disturbance as possible and the result being classified as for Rh grouping. The titres of cold agglutinin found in this way are shown in Fig. 2. In 5 cases the serum was

not examined for cold agglutinins; in only 7 out of 95 was none found. Every serum showing cold agglutination reacted with the respective patient's own cells as well as with those of others in the panel. No excessively high titres were noted. Among those showing a titre of 16 were three of the four healthy women volunteers who had been bled and transfused for red cell survival experiments. Taking this as an arbitrary limit of normal, only 9 showed a higher titre. Three of these patients had had haematemesis, one had a carcinoma of the colon, one was pregnant, one had a haemolytic anaemia, while the patient with the highest titre of cold agglutinin—i.e., 128—had leukaemia. No correlation between the titre of cold agglutinin and the number of transfusions given was noted either in the series in general or in patients whose serum was examined repeatedly in association with numerous transfusions. Fifteen patients had cold agglutinins which were also active at room temperature. In studying their sera more fully it was noted that the cells of one donor (M. S.) reacted over a wider thermal range than others in the panel. One serum (H. R.), while reacting with all bloods, including the patient's own cells, at 4° C., gave agglutination at room temperature with the cells of M. S. alone of the panel. The agglutination was present up to above 26° C. but disappeared entirely on warming to 37° C. Some 150 other bloods tested with this serum gave about 13° similar positive results at room temperature regardless of their ABO, M, N, P, or Rh types.

"Auto-agglutinins."—Two patients with haemolytic anaemia, one with an associated lymphatic leukaemia, showed auto-agglutination at 37° C., room temperature, and 4° C. The sera did not agglutinate any other than the patients' own cells at 37° C. In the blood of the leukaemic patient the agglutination of the cells was so strong that it was impossible to get an even cell suspension and to be sure of the results of Rh grouping. A similar difficulty has been reported by Reisner and Kalkstein (1942).

Discussion

Both the patients in this series who were shown to have developed irregular agglutinins present some unusual features. Mrs. M. S. demonstrates clearly the possibility of producing antibody of the Rh type after a single transfusion without previous sensitization by pregnancy. A theoretical danger is here suggested, for were she to have an Rh-positive child the infant would probably suffer from haemolytic disease, and would not escape as is usual for the firstborn. Fortunately, few people are so easily sensitized, or this would be a very real danger in giving transfusions to young women.

The other patient, Miss F. M., illustrates in the first place the possibility of immunizing an Rh-positive patient to the rh antigen. This is, of course, recognized in relation to certain instances of haemolytic disease of the newborn, but has not previously been found in response to transfusion alone. Furthermore, the development of four distinct agglutinins in response to transfusion appears to be unique. Wiener, Silverman, and Aronson (1942) have reported two cases of multiple immunization, and suggest that there exist "certain constitutionally susceptible individuals who can be easily sensitized." The findings in this series certainly bear this out. In contrast to Cases I and II, 10 of our patients received 20 pints (11.4 l.) or more of blood without developing evidence of intra-group incompatibility. One Rh-negative patient suffering from leukaemia had 30 pints (17 l.), and the patient (Miss O. T.) with aplastic anaemia has been given 184 pints (104.5 l.) over the past eight years.

With regard to the incidence of the development of irregular agglutinins, De Gowin (1945) in a series of 5,386 consecutive transfusions found 6 reactions which were attributable to Rh antigenicity. In two of these there had been previous iso-immunization by pregnancy. Young and Karihar (1945) in a series of nearly 1,000 transfusions found 5 reactions in 3 patients which were due to acquired sensitivity to the Rh factor. Two of these patients had certainly been immunized by previous pregnancies; the third may have been so, though the evidence was inconclusive. Ayer and Kammer (1944) found two irregular agglutinins in a series of 46 patients receiving 231 transfusions. In our series we have 5 antibodies demonstrable in 958 transfusions, but four of these were found in one patient.

For various reasons it seems very doubtful whether any of these series gives a true representation of the incidence of iso-immunization after transfusion. In the first place, agglutinins may be transient in their appearance and may thus escape detection if the sera have not been examined at the appropriate interval after transfusion. But the time of appearance is variable, and in some patients, as in Mrs. M. S., there may be considerable delay before agglutinins become evident. Here the antibody was detected only when the patient was readmitted six weeks after the original transfusion. In a case reported by Moloney (1945) anti-Rh was detected only on the 53rd day after transfusion, none having been found the previous week.

A further difficulty is the occasional development of the "incomplete" form of antibody (Race, 1944; Wiener, 1945), which not only fails to give agglutination but may inhibit or block the action of an agglutinin actually present. The new "Coombs test" should be of great value in investigating such cases (Coombs, Mourant, and Race, 1945).

In De Gowin's and Ayer and Kammer's series, only those patients who had transfusion reactions were investigated for the development of agglutinins. These are, of course, the patients in whom one is most likely to find such antibody, but the transfusion which stimulated the production of one of the new antibodies in our patient F. M. was unaccompanied by any suspicious reaction. This raises another point—namely, that new antibodies can be detected only if samples of the donor cells are available for setting up repeatedly against the respective recipients' sera. There are obvious practical difficulties in doing this on a large scale, and it was not attempted except in the case of F. M. The next best procedure is to set up the sera under test against a large panel of known cells and to investigate any discrepancies in the results. A second irregular agglutinin in the serum of F. M. was detected by this method at a time when the St (γ) was at its height.

Summary

Out of 100 patients transfused with 958 pints (544 l.) of blood two patients were shown to have developed irregular agglutinins.

One Rh-negative patient developed anti-Rh ($\Delta + \Gamma$ Fisher) after a single transfusion without previous iso-immunization by pregnancy.

One Rh-positive patient developed St (γ Fisher) and three new antibodies, all active at 37° C.

Cold agglutinins were found in the sera of 63 out of 95 patients examined, in titres of 1 to 128. In 15 of these the agglutinins were also active at room temperature.

In two patients an agglutinin was found which was active at 37° C. and reacted with the patients' own cells only.

We wish to thank Prof. L. J. Wits for his interest and advice, and Prof. D. F. Cappel and Dr. R. R. Race for help they have given, particularly in the investigation of Case II. We are grateful also to the blood transfusion officers for their co-operation and to the staff of the Radcliffe Infirmary, who have allowed us to study patients under their care.

Lord Rushcliffe, chairman of the Nurses' Salaries Committee, the Mental Nurses Subcommittee (appointed in association with that committee), and the Midwives Salaries Committee, has sent a letter to Mr. Aneurin Bevan, the Minister of Health, regarding the review of salaries of mental nurses and of midwives which is now being undertaken. In order to dispel any doubts which might arise while this review is taking place, Lord Rushcliffe invited Mr. Bevan to make it clear that any increases recommended following this review will have effect from Jan. 1, 1946. This is the date on which the increases of salary recently announced for certain grades of nurses became effective. Lord Rushcliffe further intimated that the method adopted in applying these recent increases will also be proposed in the case of any increases decided on for mental nurses and midwives. In his reply Mr. Bevan has informed Lord Rushcliffe that he readily accepts these proposals.

CLINICAL DIAGNOSIS OF LUMBAR INTERVERTEBRAL DISK PROTRUSIONS

WITH INDICATIONS FOR THEIR OPERATIVE REMOVAL*

BY

JOHN E. A. O'CONNELL, M.S., F.R.C.S.

Posterior crural or sciatic and anterior crural pain are familiar symptoms. In the past the commonly accepted view has been that such pain results from an interstitial neuritis of the sciatic or anterior crural nerves, or that it is referred from lesions of the muscles, ligaments, and joints of the lower back. While the milder cases recover with a variety of treatments based on these aetiological hypotheses the results of such

Table indicating the Common Clinical Features of Lumbar Disk Protrusions and Emphasizing the Signs of Localizing Value

(Level of Disk Protrusion)	L5-S1	L4-L5	L3-L4
Extradural nerve related to protrusion	1st sacral	5th lumbar	4th lumbar
Site of pain	Posterior crural—sole and lateral margin of foot	Posterior crural—dorsum and medial margin of foot	Anterior crural—medial malleolus
Site of paraesthesiae	Sole of foot	Dorsum of foot	Subcutaneous surface of tibia
Spinal deformity	Lumbar lordosis diminished Scoliosis Flexion: gross reduction	Lumbar lordosis diminished Scoliosis Flexion: gross reduction	Lumbar lordosis diminished Scoliosis Flexion: slight reduction
Spinal mobility	Extension: slight reduction	Extension: slight reduction	Extension: ? reduction more severe than with lower lesions
Straight-leg-raising test	++	++	-(+)

therapy have been disappointing in the more severely affected patients. During the last ten years much light has been shed on the aetiology of these crural pains by neurosurgeons, led by Mixter (Mixter and Barr, 1934; Mixter and Ayer, 1935)

probability if the leg pain is associated with a characteristic series of physical signs in the lumbar spine and affected lower limb (as indicated in the accompanying Table; see also Fig. 1)

Diagnosis

A variety of different lesions may occasionally give rise to the syndrome under discussion. However, experience suggests that all of these are much less common than lumbar intervertebral disk protrusions, and but three occur with any frequency. These are a tumour within the spinal canal, inflammatory or malignant disease of the spinal column (the former usually tuberculous and the latter metastatic), and spondylolisthesis. Clinical examination alone will not infrequently suggest the presence of one of these three much less common causes of lower-limb pain, but accessory methods of investigation may be required. In the first place radiography of the lumbar spine must never be omitted, and will demonstrate the presence of spondylolisthesis or vertebral disease. Further, it may show changes suggestive of the presence of an intraspinal neoplasm, and will sometimes demonstrate the existence and the level of an intervertebral disk protrusion. The latter is revealed by narrowing of an intervertebral interval and perhaps localized osteo-arthritic changes at this level. Secondly, lumbar puncture with manometry and examination of the cerebrospinal fluid may be helpful if the presence of a neoplasm is suspected, since such a lesion is much more likely to be associated with a subarachnoid block than is the usual type of disk protrusion. This is due to the fact that most lumbar intervertebral disk protrusions occupy a relatively small proportion of the spinal canal and therefore interfere little with the passage of cerebrospinal fluid to and from the sacral cul-de-sac. On the other hand, by the time a tumour lying among the roots of the cauda equina is of sufficient size to give rise to well-marked symptoms it will usually have produced a subarachnoid block—often a complete one. Thirdly, myelography with oxygen or some radio-opaque material may be required. This can certainly be helpful in atypical cases, but in the present series the procedure has been employed with diminishing frequency as experience has increased. That myelography does not necessarily lead to more accurate diagnosis is shown by the following figures. Of 39 explorations on the basis of positive myelographic findings 6 (15%) proved negative, while of 201 explorations carried out without previous myelography 7 (3.5%) were negative.

Thus it is believed that in the majority of cases the existence of a lumbar intervertebral disk protrusion can be discovered by clinical examination alone, radiography of the lumbar spine being the only accessory method of examination used as a routine. Further, it is considered that careful clinical examination will not infrequently provide evidence which allows of the location of the level of the affected disk. This belief is based upon the observation that a disk protrusion of the usual type is related to one extradural intraspinal nerve only and the theory that the majority of the symptoms and signs depend on this relationship. The clinical picture resulting from the protrusion will vary according to the particular extradural nerve affected. In the Table the clinical findings in protrusions of the last three lumbar disks are contrasted. In this table it is not intended to suggest that such clinical findings will invariably direct one to the correct level, but simply to indicate that clinical examination gives considerable assistance in locating the affected disk. Should the level first explored at operation be normal a second level compatible with the clinical picture can be readily exposed. With the modern operative technique, which necessitates the removal of only a small part of one lamina to expose an intervertebral disk, there is little disadvantage in the exposure of two disks if it appears to be indicated.

An Essential Difference

Before considering the indications for operation in these cases it is important to emphasize the essential difference between an intraspinal neoplasm and the usual type of intervertebral disk protrusion. A neoplasm gives rise to progressively increasing compression of surrounding nervous tissue. A mass of disk tissue, when it protrudes into the lumbar spinal canal, usually occupies but a small part of this canal. The dural theca will usually be slightly displaced and deformed, but it

FIG. 1—Showing extent and position of certain lumbar and sacral dermatomes (after Foerster)

evidence has gradually accumulated to suggest that, at least when the symptoms are severe, by far their commonest cause is a lumbar intervertebral disk protrusion. The presence of anterior crural or sciatic pain should therefore immediately suggest the possibility that a protrusion of a lumbar intervertebral disk has occurred. This possibility becomes a

* A paper given at a meeting of the British Orthopaedic Association in June, 1945.

contained nerve roots will rarely suffer as a result. On the other hand, the single extradural intraspinal nerve which is related to the protrusion can be displaced to a limited extent only because of its attachments—proximally to the dura and distally to the limb plexus to which the nerve passes. When the limit of possible displacement is reached the nerve will be stretched over the mass of displaced disk tissue. Were it not for its relatively fixed position in the antero-lateral part of the spinal canal the extradural nerve would be displaced like the dural theca and a protrusion of ordinary size would be almost symptomless so far as the lower limb is concerned. It is thus believed that the severity of the patient's symptoms is closely related to the degree of tension in the affected extradural nerve. With the passage of time after the occurrence of a protrusion several factors probably tend to bring about a reduction of tension in this nerve and thus a spontaneous diminution in the symptoms due to tension. The nerve may elongate before the stretching force and thus become less tense. With the passage of time the protrusion frequently tends to diminish in size and in this way the stretching force will be diminished. In cases in which the protrusion has perforated the posterior longitudinal ligament such diminution in size may be due to the loss of fluid from the protrusion—so that in time it may be converted into a low calcified ridge. When the posterior longitudinal ligament is intact it seems likely that with the patient in the horizontal position the bulge of disk tissue may be withdrawn to some extent into the intervertebral interval which previously contained it. Again, a change in relationship of protrusion and extradural nerve may bring relief—the nerve slipping from a position of tension on the summit of the protrusion to one of relaxation in a trough to either side. Here then are possible explanations of the spontaneous improvement in or even disappearance of symptoms which frequently occurs in the presence of protrusion of a lumbar intervertebral disk.

It must be admitted that when a patient's symptoms disappear spontaneously and operation is therefore unnecessary, it cannot be stated with absolute certainty that an intervertebral disk protrusion was responsible for the pain. However, there is much to suggest that the same lesion is responsible whether the pain be persistent or of short duration. Many cases in which the presence of an intervertebral disk protrusion is eventually confirmed by operation give a history of recurring attacks of pain separated by intervals of freedom. Moreover, in both groups the history and physical signs are identical. Finally, as has been indicated above, there are a number of reasons why pain due to an intervertebral disk protrusion may diminish spontaneously. It is thus believed that spontaneous recovery does occur in the presence of a lumbar intervertebral disk protrusion and, further, that it is a frequent occurrence. In the neurosurgical department in which the series of patients now under discussion were treated probably less than one patient in every three referred because of low back and crural pain is submitted to operation. Each patient must receive careful study, and operation must not be based on the reasoning that because a patient has low back and crural pain he therefore has a lumbar intervertebral disk protrusion and it should be removed. Moreover, an operation which has not been preceded by adequate study may require a wide exposure and inflict unnecessary trauma or indeed it may be performed uselessly and harmfully in the presence of some lesion other than a disk protrusion—such as, for example, a neurofibroma arising from one of the nerve roots of the cauda equina. A final reason for careful and complete examination of these patients is the advancement of knowledge which will result. Thus a better understanding of this large group of patients will be attained, and incidentally the development and disappearance of neurological disturbances due to nerve root lesions of varying degrees of severity can be studied.

Indications for Operation

The indications for excision of the intervertebral disk protrusion in these cases will now be considered. In some patients the need for operation is obvious. The pain may be intensely severe though of short duration (e.g., two months), or it may be less severe but have caused long-standing disability. At the other extreme there are patients with pain so mild or of such short duration that nothing more is necessary than to explain the

natural tendency to spontaneous recovery. It is in the case with symptoms intermediate in severity between the two of these two groups that careful judgment is required in selecting patients for surgery. Three aspects must be considered—the severity and duration of the symptoms, the severity of the neurological signs and the severity of the tension signs.

The first consideration is therefore the patient's estimate of the severity of his symptoms. This has obvious importance but is rarely enough in itself to indicate operation if not supported by physical signs. As is true in the treatment of other chronic pains, so also in crural pain it is desirable that one should submit to operation patients whose capacity to bear pain is markedly subnormal and also those who, for various reasons, may be exaggerating mild symptoms. The duration of the pain is important too. It is only in rare cases that operation has been performed for pain of less than three months' duration, and then only when it has been extremely severe. The second consideration is the severity of the neurological signs. The importance of these signs in diagnosis has already been discussed. Further, when the neurological disturbance is severe it will constitute an indication for operation. Occasionally a lumbar intervertebral disk protrusion may give rise to cauda equina injury, with the usual motor, sensory, and autonomic disturbance. Less uncommon is the group of cases in which gross weakness and sensory loss are present in one lower limb. A series of such cases in which the disk protrusion occurred during labour has been reported elsewhere (O'Connell, 1944). However in the majority of patients the neurological signs are unobtrusive and do not constitute an indication for operation. As is widely recognized, an ankle-jerk lost during an acute attack of sciatica may still be absent years after the acute pain has disappeared, and the same may at times be true of muscle wasting and areas of sensory loss. The third consideration, and certainly the most valuable indication for operation, is the severity of the tension signs. When these are well marked and the symptoms are of sufficient duration operation is clearly required.

Several of these tension signs have been discussed in a previous communication (O'Connell, 1943). It has been suggested that the diminution or absence of lumbar lordosis and lumbar scoliosis (including the alternating form) were postures designed to relax the stretched extradural nerve. The straight leg raising test was positive because hip flexion with an extended knee quickly caused a further increase of tension in the extradural nerve crossing the protrusion. Such an increase in tension would of course aggravate the patient's pain and the greater the tension already present in the extradural nerve the lower the angle through which raising of the straight leg will be permitted. A modification of the straight leg raising test which has been previously described as the drop test has been found useful (Fig. 2). Both legs are raised together to a point just

FIG. 2—The drop test.

short of that which causes pain. The sound leg is then allowed to drop to the bed, and an exacerbation of pain occurs if the test is positive—as it very often is in cases requiring surgery. Another tension sign that has been found of value in upper

lumbar disk protrusions is one which has been called the femoral-nerve-stretch test. A protrusion of the second lumbar disk is related to the third lumbar nerve and one of the third lumbar disk to the fourth lumbar nerve, and while little tension is developed in them by straight-leg raising it has been shown (by dissections) that they rapidly become tense when the hip is hyperextended and the knee flexed. In cases of upper lumbar disk protrusion the movement causes a marked increase in the patient's pain (Fig. 3).

FIG. 3.—The femoral-nerve-stretch test.

In this discussion of operative indications attention has been centred upon cases with lower-limb pain. Most of these patients have low back pain in addition, but cases are also seen in which low back pain is the only symptom, any leg pain having cleared up spontaneously. In the majority of such cases which have been seen it has been felt that an operation to remove a disk protrusion would be unsound, and they have been referred to the orthopaedic surgeon for treatment—including spinal fixation in the more severe cases. In a very few cases in which severe low back pain was associated with attacks of locking, a disk protrusion has been removed with gratifying relief of symptoms.

Conclusion

These observations are based upon the clinical and operative findings in a personal series of over 220 proved cases of lumbar intervertebral disk protrusion treated at St. Bartholomew's Hospital and in an E.M.S. neurosurgical unit during the period Jan., 1938, to May, 1945. Many of the cases have been referred to me by Mr. S. L. Higgs, at whose request I have made this communication and for whose help and encouragement I should like to express my gratitude. Among other colleagues who have referred the patients in this group to me I am particularly in the debt of Mr. L. W. Plewes and Wing Cmdr. J. H. Hunt.

The Central Council for Health Education will hold one residential summer school in England this year, at Somerville College, Oxford, from Aug. 14 to 28 inclusive. The directors of the school will be Miss D. E. M. Gardner, M.A., head of Child Development Department, University of London Institute of Education, and Dr. Robert Sutherland, medical adviser and secretary to the council. The school is intended primarily for those who have to do with the training and care of children and young people—teachers, youth leaders, health visitors, school nurses, educational and medical administrators, training organizers, welfare superintendents, sanitary inspectors, and students. The object of the school is to present the content, methods, and applications of health education. Sessions will be devoted to lectures in physiology, psychology, the biology of infection, sociology, and health, as well as to lectures, demonstrations, and discussions on the methods and applications of health education. Evening lectures will deal with wider educational, psychological, social, philosophical, and spiritual aspects. There will be opportunity for discussion under experienced leaders, for viewing health films and acquiring technique in visual aids. The afternoons will be left free for optional visits, sports, and physical recreation under expert leadership. Those wishing to book accommodation or to be supplied with further details about the school should write to the medical adviser and secretary, Central Council for Health Education, Tavistock House, Tavistock Square, W.C.1

SURGICAL TREATMENT OF DYSENTERIC LESIONS OF THE BOWEL AMONG ALLIED PRISONERS OF WAR IN BURMA AND THAILAND

BY

E. E. DUNLOP, M.S., F.R.C.S.
Lieut.-Col., A.A.M.C.

(Nakompaton P.O.W. Hospital)

Dysentery has levied a tragic toll among prisoners of war engaged in constructing the Thailand-Burma railway. Multiple diseases have been the rule and malnutrition rife. For example, numerous prisoners suffered simultaneously from dysentery, malaria, tropical ulcer, and gross malnutrition. Avitaminosis, particularly that associated with the B₂/B₆ complex, has been common. Some of the special problems in the treatment of dysentery have been:

(i) The appalling severity of the lesions, in many cases demonstrated to have *Entamoeba histolytica* infection.

(ii) The ever-embarrassing shortage, and in many cases the complete absence, of specific amoebicidal drugs.—For example, in working camps providing the most wretched conditions of life, at times not even magnesium sulphate could be obtained, and recourse was had to such pathetic devices as the administration of charcoal manufactured locally. Emetine, when available, was often obtained only sporadically, in clandestine ways, and had to be used with the utmost economy, with a view not to cure but to prolong life.

(iii) Facilities for microscopy were very frequently not available as a diagnostic aid in the early stages.

(iv) Chronicity of the bowel infection and the establishment of an "emetine-resistant" subject deriving little relief from treatment, or almost immediately relapsing.—This may be due in large part to the extremely low vitality of the individual through the multiplicity of diseases, malnutrition, and complete exhaustion. Many subjects were forced to continue working with established dysentery, and commonly months went by with only the crudest symptomatic treatment being possible, so that the bowel suffered gross damage. When this chronicity was established large quantities of emetine, even to a total of more than 50 gr. (3.25 g.) given over the period of illness, quite failed to provide relief.

Pathology

In practically all those seeking surgical relief *E. histolytica* had been demonstrated in the stools, and in most cases proctoscopy revealed typical amoebic ulceration in the lower bowel. Only one case in the series under discussion was not proved to be amoebic. Undoubtedly in some subjects both amoebic and bacillary infection were present, as reflected by the inclusion in the stools, in addition to *E. histolytica*, of a bacillary type of exudate and macrophage cells. In the acute phase of the disease, with constant passage of blood and mucus—up to 60 motions daily—ulceration was often not the usual limited and circumscribed amoebic lesion, but took on very florid forms associated with devastating lesions of the large bowel, notably a gross cellulitic swelling; and tumour formation occurred, or even huge patches of sloughing gangrene, spreading at times to the peritoneal coat. These florid lesions were chiefly in the caecal region and right half of the colon; spread to the ileum, however, was negligible.

The complication in this type of infection was all too frequently peritonitis, due either to the seeping of infection through the bowel or, less commonly, to actual perforation. In a few cases severe haemorrhage occurred, associated with passage of sloughs.

In the more common cases of prolonged chronic infection with the passage of blood, mucus, and pus over long periods, and gradual exhaustion, it was often noted at operation that inflammation, scarring, and fibrosis were present in the caeco-appendicular area. The caecum and ascending colon were fixed and indurated, with adhesions, and the peritoneal folds and

appendices epiploicae were grossly thickened. A common feature was a tendency to obliteration of the taenia and loss of haustration, the bowel being thickened, congested, and fibrosed, with roughened peritoneum and a brownish-red mottling. In two cases with no previous history of appendicitis the appendix had almost entirely sloughed away (ileostomy series). In general the appendix shared in the pathological process to a greater or lesser extent. In one case a cellulitic condition of the caecum and ascending colon of slow onset was associated with a retrocolic perforation and abscess formation (ileostomy series). Stricture formation after sloughing was met with principally in the rectum, but one patient became obstructed with a similar fibrotic process in the ascending colon near the hepatic flexure, a stricture also being present in the rectum. In two cases with gross fibrotic thickening in chronic colon lesions pathological section revealed *E. histolytica* embedded deeply in the fibrosed coats of the bowel. One interesting case of polyposis of colon and rectum requiring resection was associated with this deep infection.

Clinical Features

For the most part surgical cases fell into two groups: (1) Earlier cases of more acute nature, in which the principal difficulty was to afford relief of pain, tenesmus, wasting, deterioration, and loss of morale owing to lack of specific drugs to control the disease. For this type of case appendicectomy and caecostomy have been most effective and have certainly saved a number of lives. Indeed, the effect of this operation has in many cases been dramatic. (2) Cases of longer standing with a grossly damaged colon which, even when specific amoebicidal drugs have been repeatedly given in quantity, have failed to respond. In some of these cases, of years' duration, the complete rest of the large bowel afforded by ileostomy has been invaluable.

The Case for Surgery

Despite almost insuperable difficulties medical treatment of amoebic cases has been most diligent, and every form of available medication was tried in ingenious ways. In many cases emetine was for periods not available, and when it was it had to be used most sparingly in small courses to give the maximum life-saving effect. Ipecacuanha, emetine, emetine bismuth iodide, yatren, stovarsol, carbarsone, as well as drugs of the sulphapyridine series and sulphaguanidine, were, however, administered in quantities normally curative to many patients who finally required surgical treatment.

Bowel lavage per anum was frequently employed, using various solutions such as saline, silver nitrate, copper sulphate, potassium permanganate, eusol, rivanol, tannic acid, quinine, and yatren when available. The results were most disappointing, and in general experience cast doubts on the feasibility of thoroughly flushing out the large bowel in this way. This was mainly due to the intense irritability of the ulcerated bowel, the patient being unable to retain more than a few fluid ounces before voiding.

The failure of medical treatment and the wretched plight of dysenteric patients led to an interest in surgical relief even though surgical measures are given little prominence in standard works. In Thailand this failure led at first to the adoption of appendicectomy and caecostomy, as affording easy means of efficiently washing out the bowel. This measure began to be practised in 1943 independently in various centres such as Kanburi Hospital (MacFarlane and de Solderhoff), Takanoon (Pemberton), Tarsau and Chungkai Hospitals (Dunlop). The striking relief given to patients who seemed beyond hope caused much gratification.

In the meantime Lieut.-Col. A. E. Coates, A.A.M.C., introduced in Burma the technique of ileostomy, and on his arrival at Nakompaton stimulated interest in the hospital clinical society by showing a case in splendid condition after this operation many months previously. This case had been deteriorating hopelessly and had at no time in the course of the disease received any emetine. Lieut.-Col. Coates believed that there would be a small residue of chronic cases for which this measure would be invaluable.

It must be noted that without emetine any surgical attack on the appendix or caecum involves some danger of spread of amoebic infection to the abdominal wall. I had observed this

catastrophe in two patients previously, and was of the opinion that appendicectomy and caecostomy were much more satisfactory if a small quantity of emetine was available to follow the operation.

The freedom of the ileum from infection and the complete diversion of the faecal current by ileostomy presented arresting advantages; the only disadvantage was that a more severe second operation would ultimately be required, and that many patients felt some reluctance to endure prolonged faecal soiling. It was evident, however, that patients could enjoy perfect health without colon function; indeed they could carry on useful work, thus allaying fears that this operation was impracticable under the poor hospital conditions available and that it might upset the slender nutritional balance of those already suffering from gross malnutrition.

Operations performed at Nakompaton P.O.W. Hospital in 1944-5

Appendicectomy.—8 cases. One of these was formally closed recently, and one closed spontaneously after the disease process had subsided. The remainder have been left open as an insurance measure, despite the fact that every patient except one has regained good health.

Caecostomy.—1 case.

Ileostomy.—14 cases. Of these only the original case of Lieut.-Col. Coates has as yet been closed by a small-bowel anastomosis.

Excision of Sigmoid Colon after Transverse Colotomy.—One case of amoebic dysentery and gross polyposis of the left half of colon and upper rectum.

Resection of Right Half of Colon and Terminal Ileum and Ileotransversostomy.—One case—that of a fibrous stricturing lesion of the ascending colon. Rectal stricture was also present. Preliminary ileostomy was performed to relieve intestinal obstruction.

Excision of Rectal Stricture and Anastomosis.—One case of complete stricture of the rectum.

Spinal analgesia was employed in all cases except one in which a local infiltration was used.

Deaths

There were three deaths among ileostomy patients. Two of these were due to operation being deferred until the patients were in a moribund state, death occurring on the fourth and tenth post-operative days. The other death occurred after the patient had temporarily regained good health, and was due to intercurrent disease. In the case of resection of the right half of the colon death was due to peritonitis and acute dilatation of the stomach. The health of this patient was greatly undermined by an amoebic abscess of the liver and lung and by two serious operations for a lip carcinoma with secondary glands in the neck. In assessing mortality rates it must be remembered that all these patients were considered unlikely to survive without surgical intervention.

Nature of Operation; Complications and Results

Appendicectomy.—In all cases except two the appendix was brought out through a small transverse muscle-splitting incision in the right iliac fossa, the caecum being sutured to the peritoneum. In two cases the appendix was brought out through a small separate stab incision. In all cases the appendix was immediately divided and a tube inserted at operation. It has been clearly shown that if any difficulty is experienced in delivering the appendix there is no objection to dividing the meso-appendix, but it is necessary to leave intact the small arterial branch at the base of the organ. No cases have shown any serious infection; the wounds healed well and none have given any anxiety. One case developed a small ventral hernia after spontaneous closure. This was ultimately repaired and the stump of appendix removed. Six of the eight cases regained good health, five having passed clearance tests of more than six negative stools. Two of these received no emetine post-operatively—only bowel lavage with yatren and copper sulphate solution. One patient who appears to be in perfect health has on one occasion shown *E. histolytica* cysts in stools. Another has merely held his own, as against previous steady deterioration, and still has active infection. One case failed

to make progress, and subsequently underwent ileostomy with excellent results.

Caecostomy.—One patient, though suffering serious chronic infection, did not desire ileostomy. He had had a previous appendicectomy, so caecostomy was performed. The result has been excellent after assiduous bowel lavage. He has passed a clearance test of six stools. He still wears the tube, but without inconvenience. In many cases the complete relief of symptoms has been most dramatic with these simple operations. For example, in some instances the number of motions has fallen immediately from 20–30 a day, the patient never having more than 1 to 2 daily after operation, and blood and mucus have quickly disappeared from the stools, with rapid cessation of pain and distress. This relief is thought to be due to three factors: (i) temporary paralytic ileus of the bowel following operation; (ii) release of wind through a "bung-hole"; (iii) the effect of lavage. This undoubtedly has considerable value, as demonstrated by the relief expressed by many patients and by fluctuation when patients were moved and it was not carried out. In stubborn cases large quantities of fluid have been given by the drip method with good results. The most effective post-operative method has been a course of emetine (usually only 5 gr. (0.32 g.) available), and bowel lavage with preliminary saline followed by yatren solution 2½%. Rivanol solution 1/1000 and CuSO₄ 1/5000 have given good results. Usually not more than 5 yatren wash-outs could be carried out.

Ileostomy.—The site of election for operation has been 18 in. (45 cm.) from the ileo-caecal junction, and in six cases the incision has been a small right rectus-splitting one, with the proximal limb of the bowel at the distal extremity of the wound. In the remaining cases a small muscle-splitting incision as for appendicectomy has been employed, with the proximal limb on the medial side. One interstitial mattress stitch through an avascular point in the mesentery, together with a few sutures of the seromuscular coat of the bowel to the peritoneum, has fixed the bowel satisfactorily. In general, long exploratory incisions have not been used. In three cases a very diseased appendix was removed at operation. On three occasions the bowel was not divided at the original operation, a suture being fixed into the proximal limb through the belly wall. The procedure did not provide as satisfactory drainage as with a clean division of the bowel and for the time being the faecal current was not completely diverted, so now in all cases the bowel is divided and two tubes inserted—one for draining and the other for lavage of the colon. The main complications met with have been minor attacks of obstruction during the first month, associated with hiccup and sometimes vomiting and distension. Approximately half the cases have shown this complication in greater or lesser degree. The high-residue diet of prisoners of war has been found largely responsible, and with a strict diet of low residue it has usually been possible to leave the tube in for 7 days, until the wound has quite healed. The oedema of the exteriorized gut takes about one month to subside, and care is needed in regard to diet during that period. Lavage of the proximal limb of the ileum, together with removal of the tube and dilatation of the stoma, may be required to clear obstruction. Pituitrin has been found useful. Care must be exercised regarding fluid replacement, as in the early stages some 50 fl. oz. (1.4 l.) may drain away daily. Blood transfusions and saline administrations are often necessary in such cases. Saline is easily given by the proximal limb of the bowel as well as by other routes.

A temporary skin irritation often arises during the first few days of wearing an ileostomy bottle. These have been improvised from Dutch water-bottles, Service pattern. No serious reaction of digestive action on the tissues has occurred, but the application of serum of slaughtered bullocks has been found useful in certain cases. Usually vaseline, zinc cream, or talcum powder has been effective. The skin rapidly becomes toughened. No serious wound infections have developed. Prolapse of the intestine by intussusception has occurred in two cases—one a rectus-splitting case, the other a small transverse-iliac-fossa incision. This was readily replaced.

The general condition of these patients has been most satisfactory and their gain in weight and vigour most convincing. It is particularly noted that during the first few weeks after

operation the lower ileum to some extent takes over the function of the large bowel and the discharge becomes much thicker and less fluid. Usually blood clears up in a period of from a few days to a month, and in some cases the patients have not had any rectal motion for weeks or months except with an occasional wash-out.

In several cases no emetine could be given post-operatively, yet the patients have made good progress, gaining weight rapidly. Occasional bowel wash-outs—e.g., weekly—are useful in removing debris from the colon, but where these have not been possible some patients have gone weeks and months without any bowel action. Four who have recently been operated on are still not entirely free from rectal motions with blood and mucus; but all have made excellent progress, gaining much weight, and already are altogether brighter and more cheerful. One of these required drainage of a right-sided retroperitoneal pericolic abscess, with only intermittent discharge through the bowel.

Seven cases, representing operations performed a varying number of months ago, have all regained something like normal health and vigour, and most of these patients are quite active, eating a normal diet and doing light work. In the absence of adequate emetine two of these have had a slight relapse with passage of a little blood and mucus per rectum, but this rapidly cleared up with bowel lavage. In the remaining five, rectal lesions were observed to heal in two to three months, and more than six examinations of bowel content revealed no *E. histolytica* infection. The ileostomy bottle usually requires emptying five times in the 24 hours, but patients find life quite tolerable after the previous misery.

Closure of Enterostomy.—This step has been deferred at Nakompton pending x-ray and sigmoidoscopic investigation of the large bowel. Lieut.-Col. A. E. Coates closed the original ileostomy case brought from Burma after two years' rest of the bowel, and this patient is now in excellent health. It was noted that one case arriving at Nakompton had been previously closed by Major T. M. Pemberton, R.A.M.C., after approximately three months' ileostomy drainage. This patient has remained quite well. In general it is felt that the opening in the bowel is an excellent insurance against recurrence of active symptoms, and that the decision regarding closure is best deferred until after evacuation from Thailand.

Summary and Conclusions

Brief particulars are given of a series of cases submitted to operation at Nakompton after failure of medical treatment of amoebic dysentery infection.

The cases were all of exceptionally severe nature, and facilities for treatment were poor.

Most cases had become emetine-resistant.

Appendicostomy and caecostomy have been proved very useful measures for cases with less severe bowel damage, the infection usually being of a few months' standing. These operations have, however, given excellent results in some severe cases of long duration, and even in this type of case well deserve a trial if the patient does not desire ileostomy. More radical operation can always be done if this simple procedure fails. It is desirable but not essential to use emetine in the post-operative phase, and yatren wash-outs have been found most effective.

Ileostomy has given excellent results in the most severe emetine-resistant cases even when emetine has not been available post-operatively. It is the most certain method of arresting the disease.

Experience in Thailand has led us to believe that surgery has a definite place in the treatment of dysentery, and that early consideration should be given to this measure in cases where medical treatment has failed and the patient is continuing to deteriorate.

The results obtained by surgical methods have been due to the close collaboration not only of several surgeons but also of the physicians in charge and the pathological staff, as well as the medical orderlies, who have laboured devotedly in the operating theatre and wards. Special mention is due to the physicians especially concerned with these cases. These are Lieut.-Col. MacFarlane, R.A.M.C., Lieut.-Col. H. Larsen, N.E.I. Medical Services, and Major W. E. Fisher, A.A.M.C., Capt. J. Street, R.A.M.C.; also Major T. Marsden, R.A.M.C., for his ingenious pathological assistance.

Typical Appendicostomy Case Report

British O.R., R.A.S.C.—The onset of dysentery occurred in a Thailand jungle camp in Feb., 1943. Symptoms were very severe—approximately 20 motions daily with much blood. No emetine was

at first available, and he was treated with magnesium sulphate and potassium permanganate Lowel wash-outs. Later the patient had the advantage of 12 gr (2.13 g) emetine in 6 courses several courses of ipecacuanha 2 courses of castor oil (10 tablets) a 4 to 5 bowel wash-outs. Sulphadiazine was also tried and gave a transient fall in the number of motions. He resisted all treatment finally receiving practically no benefit from either administration. Before operation his condition was wretched. Weight 74 st (47.6 kg). He had a wasted appearance, could get no rest because of pain, tenesmus and very frequent motions and his appetite had failed. He begged for operative treatment. Abdominal examination revealed diffuse tenderness and thickening of the colon but no tumor formation. Proctoscopic examination showed very active ulceration of the rectum of amoebic type. Stool tests repeatedly showed *E. histolytica* red blood cells, and pus cells.

Operation Aug. 8, 1944.—Spinal procaine 170 mg. Morphine 1.4 gr (16 mg). A small transverse skin-areola incision as made in the right iliac fossa and the muscles were split. The caecum was thickened, indurated, and bound down to the right iliac fossa by adhesions. The appendix was large, thickened, congested and indurated, and was found in the ilio-caecal anastomosis. No ulceration of the mucosa was seen. To mobilize the appendix most of the meso-appendix was clamped and tied leaving the arterial branch at the base, the appendix was then brought out of the wound and the caecum sutured with fine silk through the peritoneum. The peritoneum was closed with catgut, the muscles with catgut, and the skin with silk-worm gut. Fine transfusion tubing was passed into the appendix to the caecum at a point 1 in. (2.5 cm) from the abdominal wall to which the tube was then anchored with a stitch. Dressings of soft paraffin and tinct. benzoini com. were applied.

On the first post-operative day yareten wash-outs 2½% preceded by saline 1 pint (465 ccm), five daily wash-outs with yareten solution were given followed for a time with copper sulphate 1/1000 daily. Emetine was available on the fourth post-operative day, and 5 gr (0.32 g) was followed by a course of emetine bismuth iodide 15 gr (1 g). The wound healed by first intention, sutures being removed on the seventh day. The stoma was excellent with a mucocutaneous junction. There was no untoward reaction.

Progress.—By the fourth post-operative day the patient had one motion daily, firm and almost clear of blood. Appetite improved right from the start and the pain disappeared. In four months he had put on over 7 st (19 kg) in weight. Proctoscopy in Feb. 1945 revealed a healed rectal mucosa. Now, after twelve months he is perfectly healthy, and has had no relapse, he has gained nearly 4 st (25.4 kg) in weight and works as a voluntary orderly. All stool tests have been negative—the last a series of six done in Aug. 1945. The appendicostomy stoma causes no particular inconvenience.

STREPTOCOCCAL MILIARY INFILTRATION OF THE LUNGS

WITH DESCRIPTION OF A CASE

BY

PHILIP ELLMAN, M.D., F.R.C.P.

In Charge of Medical Division, Leatherhead Emergency Hospital etc

The existence of an infiltration of lung tissue, giving rise to radiological shadows almost identical with those of pulmonary tuberculosis but not apparently connected with the tubercle bacillus is well known (Scadding 1937, and others). In a consideration of the aetiology of subacute pulmonary infections (Davidson and Ellman, 1941) attention was drawn to the fact that many pulmonary lesions are now brought to light which, before the days of adequate x-ray examination, passed undetected, and while in most of these the nature of the disease is not in doubt, in many the differential diagnosis is still a matter of considerable difficulty. In other words, radiological diagnosis no less than physical diagnosis has its limitations, nor does it always provide a short cut to that understanding of the morbid anatomy of disease which can be reached only by a synthesis of all the available data.

Since the publication of the above mentioned paper I have encountered a number of acute and subacute non-tuberculous pulmonary infections closely simulating, in their clinical and radiological appearances, pulmonary tuberculosis but showing signs of healing by natural resolution within a relatively short period. In some such cases the streptococcus has undoubtedly been a causal organism. A case of an apparent acute streptococcal miliary infiltration of the lungs is now described.

History of Case

Miss A., aged 20, was admitted almost moribund as a case of acute febrile emia to Leatherhead Emergency Hospital on Aug. 1945. She possessed a picture of gross anaemia and a violent infection. She gave a history of increasing fatigue, weakness and pallor over the past two to three months. Her period, previously irregular but normal, had during that time been scanty. Immediately before admission, in addition to aggravation of these symptoms she had noticed acute dyspnoea on exertion, attacks of giddiness and palpitation and a slight cough on the morning of admission. There was a loss of any obvious loss of weight. During the evening of 19-5 a slight pyrexial attack was accompanied by a sore throat and a cough with a little yellowish sputum. She also had a severe haemorrhage after which the sputum was blood-stained. The attack lasted two weeks and was followed by a similar attack, followed by the haemorrhage a few months later. There was otherwise no noteworthy previous history. The family history was otherwise normal and her occupation was of no significance so far as her illness was concerned. Seven weeks before the onset of this illness she had attended a mass radiography clinic when her lungs had been reported as clear.

On admission she was grossly anaemic, so weak that she could not walk. Her respirations were shallow and rapid (6) to

FIG. 1.—Diagram of chest from a case of acute streptococcal miliary infiltration of the lungs.

pulse was thin, rapid (120) and irregular, temperature 101°. Examination of the lungs showed scattered crepitations throughout both lung fields and broncho-vesicular breath sounds. The heart was not enlarged clinically, the rhythm was regular, the heart sounds were very faint, there were no significant murmurs, the blood pressure was 100/60. There was no lymphadenopathy, or splenomegaly. Examination of the fundi showed them to be normal, but a large haemorrhage was seen in the right retina. A blood count showed a haemoglobin of 23%, the white cells numbered 26,000, mainly polymorphonuclear in type, otherwise there was nothing significant in the differential count. X-ray examination of the chest showed diffuse miliary infiltration of all zones of both lungs but the apices were singularly clear (Fig. 1).

The next day her pulse was more regular and the respirations no longer so shallow. The physical signs in the chest were unchanged and the temperature was still 101°. Following half a pint (254 ccm) of blood, given very slowly, her haemoglobin rose to 70%, the white cells numbered 23,000 (polymorphs 90%). She was given large doses of iron and ascorbic acid, and 3/4 pint (426 ccm) of concentrated blood again that night. On Aug. 7 the physical signs in her chest were

less marked; the respirations were still raised (34), but they were not quite so shallow. The haemoglobin was now 36%. Repeated examination of the sputum (laryngeal mirror) showed an almost pure growth of haemolytic streptococci, but no tubercle bacilli.

Penicillin, 20,000 units three-hourly, was started soon after admission, a total of 960,000 units being given in six days. Two days after beginning the penicillin (Aug. 9) her temperature had dropped to normal, the respirations were 28, and the haemoglobin had risen to 40%; the retinal haemorrhage was still visible. A day later her respirations had also dropped to normal; the physical signs in the lungs were markedly diminished and the adventitious sounds were confined to the bases. Her haemoglobin continued to rise steadily.

Serial x-ray examination of the chest showed progressive resolution, and within ten days the miliary infiltration had completely

FIG. 2—Skiagram of same case, showing complete resolution

resolved (Fig. 2). The retinal haemorrhage had also resolved and the blood count had become entirely normal. A gastric residuum at this time showed that the patient was achlorhydric.

Discussion

The rôle of the streptococcus in pulmonary infections of an acute pneumonic or bronchopneumonic character, as well as varied subacute pulmonary infiltrations of similar aetiology, is significant, although in some cases debatable, and there is an increasing literature on this subject. In the case I have recorded the sputum was collected on a laryngeal mirror and precautions were taken to avoid contamination by mouth organisms. A heavy growth of haemolytic streptococci was repeatedly found and, bearing in mind the severe toxæmia and the clinical and radiological lung findings, there was undoubtedly a haematogenous lung infection of streptococcal origin. Admittedly, many bacteriological examinations of sputum will show a mixed aetiological flora, including streptococci, but in this case the sputum, apparently uncontaminated, contained on each occasion an almost pure growth of haemolytic streptococci.

Twining (1938), among others, records that streptococcal pulmonary infections may closely simulate acute or chronic pulmonary tuberculosis. Miliary infiltrations of the lung, apart from those of a tuberculous nature, may occur as a miliary erythematosis, in silicosis, in bronchiolitis (particularly following influenza and measles), in Hodgkin's disease as a lymphadenomatosis, in leukaemia, in certain pulmonary mycoses, in blastomycosis, in Bock's sarcoidosis, in miliary amyloidosis of

the lung, in miliary stasis of the lung with mitral stenosis, etc. Twining also refers to a case of bronchiolitis obliterans described even at necropsy as a miliary tuberculosis until histological sections finally disproved this. The case was reported by Assmann, and was an end-result of influenzal bronchiolitis.

I use the term "miliary" in this case because the radiological appearances of the lung simulated a miliary tuberculosis. Gloyne, in a personal communication, informs me that he has seen, at necropsy, several cases of an acute streptococcal disseminated bronchopneumonia, in some of which "silicosis" had been suspected; and in the present case some would perhaps have used the term "disseminated streptococcal bronchopneumonia." My own feeling, however, is that the miliary nature of the radiological appearance of the lungs more than justifies the description "streptococcal miliary infiltration of the lungs." It is of interest to note that in the case here reported the apices were not involved in the skiagram.

It is presumed that this patient had had a simple achlorhydric anaemia for some months and that an added streptococcal infection at this stage had rendered her a victim of streptococcal septicaemia with a pulmonary localization of a miliary nature. I have not been able to find a similar case in the literature.

Summary

A case of simple achlorhydric anaemia complicated by the sudden onset of acute streptococcal septicaemia with miliary pulmonary localization is presented. A dramatic response to penicillin therapy (aided by transfusions and iron therapy for the anaemia) resulted in complete resolution of the lung lesion.

I am indebted to Dr. D. Nabarro for the pathological investigation.

HEREDITARY CLUBBING OF DIGITS IN TWO FAMILIES

BY

ELI DAVIS, M.D., M.Sc., M.R.C.P.

Deputy Medical Superintendent and Physician, St. Andrew's Hospital (L.C.C.)

The whole question of clubbing of the digits was reviewed in detail in 1942 by Mendlowitz, and he included a discussion of hereditary clubbing in which different fingers or toes may be involved in varying degree. Some fingers or toes may be spared but thumbs are nearly always included. Usually the patient cannot remember ever being free from clubbing, but the condition may become more pronounced in middle life. Horsfall (1936) described three families with a total of 20 cases, the abnormality occurring in four generations in one family. In 18 of his 20 cases all the digits were clubbed in the affected members, but in the other 2 cases (belonging to one family, with 10 affected members) only a minority of digits were involved.

Personal Cases

In the first family I encountered (see family tree, Fig. 1) all the affected persons had bilateral symmetrical clubbing involving the first three fingers (Fig. 2) and toes. The fourth and fifth digits were quite normal. Clubbing varied in degree from member to member, and became more pronounced with increasing age. All the affected members, and many others, had webbing of the second and third toes.

In the second family (Figs. 3 and 4) the defect was in the little finger only, and was asymmetrical. Thus in the mother the left little finger was much more affected than the right, whereas in the three affected children the right little finger was chiefly involved. Toes were normal in this family, and webbing was absent. The mother stated that neither her siblings nor her parents were affected.

Skiagrams showed shortening of the phalanges of the affected digits in both families. There was no disease associated with the clubbing in these families.

Capillary Microscopy

Mendlowitz pointed out that studies of clubbed fingers by capillary microscopy had yielded results of doubtful value. I found that, in clubbing, capillaries are generally but not invariably much lengthened and congested, with a tendency to

FIG. 1.—Tree of Family 1. Hereditary clubbing of first, second, and third fingers and toes—bilateral and symmetrical.

FIG. 2.—Photograph of hands (Family 1)

FIG. 3.—Tree of Family 2. Hereditary clubbing of little finger.

FIG. 4.—Photograph showing clubbing of little finger (Family 2)

formation of (microscopic) petechiae. In these families capillary microscopy showed no difference whatever between the clubbed fingers and the normal fingers. In the first family capillary microscopy was done on one affected member only. In all fingers there was the usual number of capillaries per field; but they were long, with wide loops and wide limbs, and blood-flow

was rapid. In the second family capillaries were studied in two affected members. They were normal.

I thank Mr. J. R. M. Whigham for his help, and Dr. J. E. McCartney and Mr. J. Andrews for the photographs.

Medical Memoranda

Leiomyoma of the Ileum producing Intussusception

The following case is considered worthy of record in view of the relative rarity of the condition.

CASE REPORT

A man aged 41 was admitted to Llandough Hospital, Cardiff, on Nov. 23, 1944, with a history of pain in the upper abdomen for about 3 to 4 years. The pain came on half to one hour after a meal and was relieved by alkalis. Three months prior to admission he noticed that he was becoming constipated, and the night before he entered hospital some blood was passed per rectum. In addition, for about two months there had been pain in the region of the umbilicus. The day before admission a barium meal had been given, and this induced severe abdominal pain.

On examination his general condition was good and, apart from tenderness in the right iliac fossa, no other abnormal signs were elicited. On Dec. 14 a palpable mass was found in the right lower abdominal quadrant. A barium meal and follow-through revealed no lesion in the stomach, duodenum, or small intestine, but the occult blood was positive on two occasions. Subsequently a barium enema was given, and this revealed an obstructive lesion in the upper part of the ascending colon.

Laparotomy was performed on Jan. 3, 1945, and this revealed an ileo-caecal intussusception, with the apex lying about halfway down the ascending colon. Reduction by the usual technique was easy, and examination showed the apex of the intussusception to have been occupied by a tumour of the ileum. The tumour, which was endo-colic, was situated approximately 6 in. (15 cm.) from the ileo-caecal valve. Accordingly about 8 in. (20 cm.) of terminal ileum containing the tumour was excised and continuity re-established on end-to-side ileocolostomy. Convalescence was uneventful, and he was discharged from hospital on the 15th post-operative day.

Examination of the excised specimen showed a firm mass about the size of a walnut, projecting into the lumen of the gut, its surface being lobulated.

Pathological Report.—"The tumour is a submucosal leiomyoma, which is forming a polypoid mass projecting into the lumen of the intestine. Histologically it appears unusually vascular in parts and there is some ulceration on the surface, but there is nothing to suggest malignancy."

COMMENTARY

Leiomyoma of the small intestine is uncommon. Smith (1937) collected 109 leiomyomata of the small intestine, and Horsley and Keasbey (1939) reported 15 additional cases. Morrison (1941) in a series of 21 benign tumours of the small intestine found 2 cases of leiomyomata, both in the ileum; and Golden and Stout (1941) recorded 6 cases—two duodenal, one jejunal, and three ileal locations. Weber and Kirklin (1942), analysing a 32-year period at the Mayo Clinic, found 14 cases of small-gut leiomyomata in a collection of 41 benign tumours. These tumours are more common in the ileum than in the jejunum or duodenum (Moore and Schreisser, 1934; Railford, 1932), the average age incidence being 30 to 40 years (Rankin and Newell, 1933).

The two outstanding features of the reported cases are mechanical obstruction and melæna. In the submucosal variety the commonest presenting finding is intestinal obstruction due to intussusception, while in the subserosal variety melæna is the principal clinical feature (Smith, 1937).

The case here recorded confirms Smith's finding that submucosal leiomyomata tend to cause intussusception.

I am indebted to Dr. Jethro Gough, of the Pathology Department of the Welsh National School of Medicine, for the pathological report.

Reviews

PRINCIPLES OF HUMAN PHYSIOLOGY

Principles of Human Physiology. Originally written by Prof. E. H. Starling. By C. Lovatt Evans, D.Sc., F.R.C.P., F.R.S. Ninth edition. Chapters on the Special Senses by H. Hartridge, M.D., Sc.D., F.R.S. (Pp. 1,155; 668 illustrations, 7 in colour. 36s.) London: J. and A. Churchill. 1945.

The 9th edition of the *Principles of Human Physiology* appears without its former prefix and is now more closely associated with Prof. Lovatt Evans, who has actually been responsible for the work since the 4th edition. While it is true that the main emphasis in medical education should be the inculcation of fundamental principles rather than a mass of factual knowledge, it is nevertheless necessary to remember that these same principles are derived from facts. It is a merit of the book that physiology is presented as an experimental science. Probably because of this outlook the author has never claimed that the work should be a text in clinical physiology, although the requirements of the medical student are fully met and full use is made of clinical references. Though it may not be the easiest book for the student to work from, there can be little doubt that with the aid of good teachers, who will assist him to obtain the right perspective, he will find "Starling" gives him a lasting foundation on which to build his physiological knowledge and its clinical applications.

There are no great changes in the general arrangement of this edition, but rewriting in many places has served not only to bring the work abreast with recent knowledge, as in the sections dealing with electrical exploration of the nervous system, or lymph formation, but also to emphasize the co-ordinated working of the different systems of the body, which is the essence of modern physiological thought. This approach to the subject is shown by some examples from the headings of the different sections of the book: Systems for Distribution of Materials—Blood, Circulation and Respiration; The Intake of Materials—Nutrition, etc.

An innovation is the prefacing of the chapters by historical notes; and although they are perhaps too short to be of value in themselves, yet they should serve as useful stepping-stones to historical reading for the many students who will continue to use this textbook.

THE FIRST THOMAS WAKLEY

Battling Surgeon. By Charles Brook. (Pp. 176. 2s. 6d.) Glasgow: The Strickland Press. 1945.

If I cannot subscribe fully to Dr. Brook's hero-worship, I can congratulate him heartily on a very interesting book about a man to whom our profession can never be too grateful. But when he says, "I say, and I say it with emphasis, that great as Joseph Lister was, he was a mere pygmy by the side of Thomas Wakley," I cannot help feeling some doubt as to his sense of proportion. But I can go a long way with him in his admiration for Wakley, for I was, so to speak, "brought up on him." The country doctor to whom I was acting as a very young unqualified assistant had a long series of early volumes of the *Lancet* in which I browsed and thereby imbibed a taste for the politics of our profession and an unholly and quite uncritical admiration for Wakley's gift for invective. Those were the days in which antagonists in the press and on the platform had no use for the rapier. Wakley was an expert with the bludgeon and obviously enjoyed using it. Resisting temptation, I shall give only one example quoted by Dr. Brook. Wakley was bestowing a parting benediction on the editor of a rival journal which had just expired. "He is a disingenuous without plausibility and dishonest without astuteness. He had the wriggling lubricity, without the cunning, of a serpent."

If we are occasionally repelled by the brutality of his language, we must not forget that Wakley was living in a medical world in which abuses were rampant. Few men can have had a fuller life; a medical student (on very short commons), a practitioner for a time in London, the founder and editor of the *Lancet*, and, along with this, coroner and Member of Parliament. In each of these fields he made his mark as a reformer, and in spite of his pugnacity became a

popular national figure respected even by his opponents. He gained his spurs as a fighting man by his attacks in the young *Lancet* on the almost incredible nepotism and corruption on the staffs of the London teaching hospitals. He published, for the first time, reports of hospital lectures and operations accompanied by scathing criticism. He naturally found himself in the Law Courts. Indeed, for many years he lived in a vortex of legal actions, generally as defendant, and often proved himself equal to the greatest advocates of the time. His next great attack was on the unreformed College of Surgeons. This brought him more enemies, but he wore most of them down and did much to accelerate reforms which have made the College what it is now. His Parliamentary career was unusual. It was only at the third attempt that he carried the Finsbury Division as an independent radical. He refused to do any canvassing and his supporters paid his expenses. Thereafter he was returned as long as he was willing to stand. We owe him many legislative reforms, and not all of them in the medical field. It was his pioneer work which led to the Medical Act of 1858, still the basis of our legal position as a profession. He got power for coroners to pay for a post-mortem examination; he successfully opposed a clause in the Vaccination Act of 1840 which would have confined vaccination to Poor Law medical officers; and was largely instrumental in so altering the law as to make the operations of the "resurrectionists" unnecessary. He was trenchant in his criticisms of the conditions in lunatic asylums. As coroner for West Middlesex he conferred a new dignity and usefulness on that office, was strongly in favour of medical coroners, and was the chief figure in several important cases arising from inquests, the most outstanding being that of a soldier who died as a result of flogging. This led to its practical discontinuance.

The *Lancet* under his charge did great public work, as, for example, in the exposure of the adulteration of food, milk, and water, and legislation followed. There was, indeed, hardly any social abuse prevalent at that time which the *Lancet* did not tackle—generally with effect. The book is very good value for 2s. 6d. It would be well worth the money if it were only for the brilliant character sketches of most of the leading medical men of the time. It deserves to be read by everybody interested in how our social reforms have come about, and who is thankful to those who, in face of immense difficulties, made advances possible. Our profession may well be proud of Thomas Wakley and grateful to Dr. Brook for reminding us of him.

ALFRED COV

SEMINOLOGY

Studien am Menschlichen Sperma. By Charles A. Jochl. (Pp. 154.) Basle: Benno Schwabe and Co. 1942.

This book provides a concise exposition of the methods employed in studying human semen. The technique closely follows the lines described in other textbooks on the subject. One original process deserves attention: a method is described for embedding the formed elements of semen in paraffin for sectioning. This allows a more thorough cytological study of the cells of spermatogenesis which are too scanty in the smear preparation. The author claims that changes in spermatogenesis—e.g., as the result of treatment—appear in these cells before the spermatozoal picture alters. If this is so the laboriousness of this method would be amply repaid. The findings of over 1,300 semen analyses and post-coital tests are evaluated, and an appendix containing excellent histological illustrations clarifies doubtful points of nomenclature.

The author's exposition is clear, and his approach to the subject entirely practical. His book is a good introduction into a comparatively unexplored field of clinical research.

A third edition of SANFORD R. GIFFORD'S *Textbook of Ophthalmology* is published by W. B. Saunders Company at 20s. It covers the elementary aspects of ophthalmology concisely and adequately. It contains rather less obsolete teaching than is usual with books of this size, as is seen in the excellent account of retinal arteriosclerosis, but it also slips up badly in its occasional adherence to obsolete teaching, as instanced in the section on the treatment of ophthalmia neonatorum.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 26 1946

VACCINATION AGAINST INFLUENZA

The use of virus vaccines for protection against influenza has hitherto given either inconclusive or frankly disappointing results. Undaunted by these, the Commission on Influenza in the U.S.A. pursued endeavours in this direction in the early years of the war, and were able by the autumn of 1943 to stage a full-scale trial. A full description of this trial and its results has made a rather belated appearance in a series of 7 papers¹ which together form a massive contribution to the literature of this subject. The introductory paper by Francis gives a general account of the methods used and of their evolution. The vaccine was derived from egg allantoic fluid, and virus from this source was concentrated tenfold by adsorption on chicken erythrocytes; each dose of 1 ml represented 2.5 ml of allantoic fluid containing the PR8 strain, 2.5 ml containing the Weiss strain (both of type A), and 5 ml. of the Lee strain (type B). It was preserved with formalin and phenyl mercuric nitrate, and shown to retain its potency in this condition. Of the populations studied, one half received a single dose of 1 ml of this vaccine, while the remainder were given an injection of saline with the same two preservatives added; thus not even the sensation produced by the inoculation enabled the recipient to guess whether he belonged to the treated or to the control group. The majority of the subjects were university students in "Army Specialized Training Programme" units; the status of such a student is not quite clear, but they appear to have been housed together and subject to discipline. Regular sick parades were held, and all men diagnosed as having influenza were placed in hospital. In a considerable proportion of vaccinated and controls and in most cases of clinical influenza repeated antibody titrations were carried out, sometimes by several methods and with the use of more than one strain of virus. The virus in cases of influenza which occurred was also identified at every centre.

At each of six centres—two in New York State, and the remainder in the Universities of Minnesota, Iowa, California, and Michigan—the total number of men studied was over 1,000. Vaccination was done in November, 1943. The astonishing feature of this experiment is that influenza, proved at every centre to be due exclusively to type A virus, broke out almost immediately afterward. In two centres the beginning of the outbreak was simultaneous with vaccination, and elsewhere the first cases occurred within a few days or up to a fortnight; only in California was there an interval of about a month before the first cases and two months before the epidemic reached its peak. From five centres the reports are unanimous in recording that vaccinated subjects had less influenza than controls. The experience of Minnesota is typical, the percentage of vac-

inated men developing influenza being 2.7 and of the non-vaccinated 9.06. The difference was nowhere less than 2-fold and at two centres it was over 4-fold. In California, on the other hand, although there was some difference in favour of the vaccinated group in the frequency of influenza, it proved to be due to type A virus, the total cases of clinical influenza, including those not tested for virus and those in which such a test was negative, are almost identical. This series alone can be interpreted only as meaning that the vaccine was without effect.

The sole ostensible difference between California and the other centres is in the time elapsing between vaccination and the appearance of influenza. If this were the explanation it would almost condemn the method in itself, since an immunity so transitory would be of value only in the gravest emergency. That it is not the explanation is suggested both by the fact that the antibody level following vaccination remains high for months, and by observations pointing to another and almost equally disturbing reason. It has been recognized for some years that different strains of type A virus vary antigenically, and further evidence of such differences was obtained in these studies. At Michigan the correlation between serum antibody level and the frequency and severity of influenza was close when the Weiss strain was used for titrations, but the results with the PR8 strain were less conclusive. It seemed, therefore, that the Weiss strain, which was contained in the vaccine and had been isolated only six months before, was closely related to, if not identical with, that responsible for the epidemic. In California, on the other hand, serum antibody titrations were done not only with these two strains but with a third isolated during the epidemic itself. Perhaps the most striking figures emerging from these studies are the ratios between increase in titre due to infection and that produced by the vaccine. These were, using PR8 1.8, Weiss 4.1, and Olson (the current strain) 3.7. Analysis of the same data shows that according to titrations employing PR8 the antibody responses to infection and vaccination were equal, whereas in tests with the Olson strain infection caused a mean increase 3.7 times greater than that produced by vaccine. One cannot avoid the conclusion that the California outbreak was due to a virus differing antigenically from those in the vaccine to such an extent as to deprive this vaccine of almost all protective power.

It is as well that this single negative result was obtained, or those at the five other centres might have encouraged a far too optimistic outlook. It seems that the study of influenza increases yearly in complexity, and this increase keeps pace with and neutralizes the effect of every advance achieved. What limit is there to the possible subdivision of type A virus? And may not its variety account for the transient immunity produced by the attack itself? This has always been a serious stumbling-block to any belief that artificial methods can achieve worth-while immunity. We can only conclude for the time being that vaccination against influenza has not yet passed beyond the experimental stage, and that only further studies of this most laborious nature will illuminate the subject further. It may perhaps also be concluded that should a catastrophic

war just as after the last, a vaccine prepared from the current strain of virus should if possible be used. Whether it could be prepared in sufficient quantity soon enough is another matter.

INTERNATIONAL HEALTH ORGANIZATIONS

The charter of the United Nations, adopted by fifty Governments at San Francisco in the spring of last year, entrusted the solution of health problems in the international field to the new United Nations Organization (the word "Organization" has now been dropped from the title), and at the instance of the Brazilian and Chinese delegations it was agreed that in preparing a plan for the new international health structure methods of associating it with existing institutions should be fully considered. It is useful, therefore, to recall what official international health organizations are already in being, most of them dating from the interwar or recent war period, though two of them go back to the first decade of this century.

The organizations which are devoted wholly to public health are the International Public Health Office in Paris, the Health Organization of the League of Nations in Geneva, and the Pan-American Sanitary Bureau in Washington. The first of these, established in 1909, is designed to provide a link between the signatories of the various international health Conventions, beginning with a Convention signed at Venice in 1892 with the object of preventing cholera from reaching the Mediterranean area, right down to the International Civil Aviation Convention formulated in December, 1944, and not yet in force. The Paris office acts as an information centre and supervises the application of the Conventions. The Health Organization of the League of Nations, set up under the Covenant in 1921, is the most ambitious of all the bodies. It consists of a general advisory council, a health committee with various commissions and subcommissions, and a Health Section which forms part of the Secretariat of the League. Its work falls roughly into two parts: the first is concerned with the prevention of disease, including epidemics, and the second with the promotion of health, including the study of such factors as nutrition, housing, and physical education. The work has had a wide range, but the most important activities have been the service of epidemiological intelligence, the exchanges of health personnel between different countries, and the assistance of Governments in establishing or reorganizing their health administration. The Pan-American Sanitary Bureau in Washington, with branch offices in Central and South America, derives from a conference of twenty-one American republics in 1901-2. It is a centre for co-ordination and information in the field of public health in the Western Hemisphere, and its primary interest is in staying the spread of communicable diseases.

All these organizations are solely concerned with health functions. In addition there are others which have public health as one of their interests. The International Labour Organization, set up at Geneva after the war of 1914-18, includes in its work the study of industrial hygiene, the prevention of industrial diseases, and the protection of workers against health hazards. U.N.R.R.A., which began

its work in 1943, has as one of its purposes "to aid in the prevention of pestilence and the recovery of the health of the people." The United Nations Food and Agriculture Organization, deriving from the Hot Springs Conference in 1943, seeks to raise the levels of nutrition and the standards of living everywhere. Then there are two regional bodies: the Anglo-American Caribbean Commission, established in 1942 to deal, among other matters, with the improvement of nutrition, housing, and public health; and, most recent of all, the Arab League, established in 1945 to facilitate co-operation between the Arab independent States in health questions among others. These are all official organizations. In addition there are voluntary ones such as the International Red Cross and the Rockefeller and Millbank Foundations, whose beneficence has spread far beyond national boundaries. Other important links are the international congresses, dating from the first medical congress in Paris in 1867 and the first surgical congress, also in Paris, in 1885, and again the intellectual traffic between the medical faculties of the universities of different countries.

The United Nations Information Organization (38, Russell Square, W.C.1) devotes its Information Paper No. 5 to a brief account of these bodies and a recital of the international sanitary Conventions of the last fifty years. The information is timely in view of the present assembly of the United Nations in London, when health questions may well influence some political decisions.

MODE OF ACTION OF SULPHONAMIDES

For some time after the discovery by Fildes and Woods in 1940 that *p*-aminobenzoic acid neutralizes the action of sulphonamides on bacteria it seemed that the mystery of how these compounds act had been completely solved. Further than that, the search for "antagonists" was widely pursued as a method for elucidating chemotherapeutic effect: the fact that no known naturally occurring substance antagonizes the action of penicillin is both a reason for its powerful chemotherapeutic effect and an obstacle to further understanding of how that effect is produced. But the further study of sulphonamide action has produced a more complicated picture altogether, and it seems that the Fildes-Woods theory can no longer wholly explain the ascertained facts. These complex developments are very fully reviewed by R. J. Henry,¹ whose monograph, which concludes with nearly 700 references, is one of those compilations without which few people can hope to follow the progress of present-day academic work.

The line of the argument pursued may be stated briefly as follows. It is generally agreed that sulphonamides prevent bacterial growth by inhibiting one or more enzymes. According to the Fildes-Woods theory the enzyme concerned is responsible for an anabolic reaction of which the substrate is *p*-aminobenzoic acid. Direct proof of this is lacking, and a serious difficulty in accepting this as a complete explanation is that sulphonamides are antagonized by so many substances other than *p*-aminobenzoic acid itself. These include methionine, other amino-acids, and urethane among substances of known composition, and proteins, peptone, bacterial products, and unknown elements in tissues and exudates. Another possibility is that sulphonamides inhibit oxidation-reduction enzymes, and this is an

¹ *The Mode of Action of Sulphonamides*. By Richard J. Henry. Publication of Josiah Macy Foundation, Review Series, 1944, vol. 11, No. 1, pp. 72, 698 (refs.).

explanation which Henry favors although he emphasizes that here again actual proof must await the results of further work.

It is significant in this connexion that sulphonamides are known to depress the activity of a wide variety of living cells other than bacteria, including fungi, higher plants, protozoa, and mammalian tissues. Decreased oxygen consumption has been shown to accompany this effect in many cases. One of the most interesting of these is the action on sea-urchin eggs, but here sulphanilamide inhibits the respiration and division of fertilized eggs but does not affect respiration in the unfertilized egg except in exceedingly high concentrations. Here therefore is an example of a cell in which there must be two respiratory systems—one of which furnishes the energy for cell division and is inhibited by sulphanilamide whereas the other is not. If a similar mechanism exists in bacteria the fact that oxygen consumption continues after cell division has stopped is no objection to the hypothesis that sulphonamides inhibit respiration; they may inhibit only that fraction of total respiration which provides the energy for division. These and other studies on respiration tend to class the sulphonamides with "indifferent inhibitors" such as narcotics. We have been accustomed to thinking that under the influence of sulphonamides bacteria are overcome by starvation—it is an even more attractive thought that the effect is to put them to sleep.

WORK FOR SILICOTIC MINERS

"Provision of Employment in South Wales for Persons Suspended from the Mining Industry on Account of Silicosis and Pneumoconiosis" is the title of a 6 page White Paper presented by the President of the Board of Trade to Parliament in December¹. This embodies the findings and recommendations of a "Working Party" which the President of the Board of Trade and the Minister of Labour sent to investigate the problem. The party consisted of Mr D. R. Grenfell, M.P., and another local M.P., two trade union leaders who are themselves silicotic, four representatives of local authorities, and three departmental members. Of the ten experts consulted six were medical officers. Silicosis and pneumoconiosis are due to the effect of dust in the lungs. X-ray examination reveals fibrosis in nodular form in silicosis, whereas in pneumoconiosis it appears as reticulation. Medical knowledge is incomplete, but pneumoconiosis may be accepted as the early stage along the road to silicosis, hence the importance of quickly removing suspected victims from the mines in the initial phase. Medical evidence is unanimous that if this is done the progress of the disease is arrested. Persons affected fall into two categories: (a) the vast majority who are capable of employment in any light industry which does not involve working in dust or fumes and does not require heavy lifting, but it is important to avoid long distance travelling to work, (b) a limited number of special cases that need "sheltered" employment under special conditions. The investigators are satisfied that those in the first category can engage in ordinary light industry under normal industrial conditions, and that this class of workers, in their own interests, should not be segregated from their fellows. They advise that a small number of factories should be built by the Government in South Wales and Monmouthshire through the Trading Estate Company, Ltd., in advance of a demand from tenants in selected areas containing large numbers of disabled unemployed, and that the use of these premises should carry an obligation to employ a

minimum percentage of disabled persons as defined by the Disabled Persons (Employment) Act 1944. Such Government-owned factories would need to be built without delay and located at five focal points. The recommendations are set out in precise terms. They would ensure employment for men in areas where this is a highly desirable and otherwise difficult to obtain; they would give an indirect but real preference to persons suspended from the mining industry, and they can be put into operation at once and administered within the framework of existing legislation. Action on the lines proposed ought to be taken towards rehabilitating ex-miners in South Wales who suffer from silicosis and pneumoconiosis.

BACTERIAL DESTRUCTION OF CONCRETE

The serious corrosion of concrete caused by bacteria is a new phenomenon. The production of sulphuric acid is an essential part of the process but the reactions involved are of great complexity, and a complete explanation of the mechanism is far from easy. There has been increasing evidence that some of the sulphur bacteria are at least in part, responsible for the damage. Bunker in a review of the physiology and biochemistry of the sulphur bacteria states that destruction of concrete occurs in circumstances in which much hydrogen sulphide is formed on bacterial action, and suggests that this is oxidized non-biologically to sulphuric acid. Recent evidence, however, suggests that the oxidation is in part a biological process. Parker² working in Melbourne, has investigated a number of cases of destruction of sewers in which decay has taken place just above the water line, the cement of the concrete being reduced to a putty like mass containing embedded particles of gravel. In all cases the damage was associated with sewage containing considerable quantities of hydrogen sulphide. The rate of corrosion is particularly rapid in the first period, up to 2 years during which corrosion is little apparent, then a period of very rapid destruction. Parker has isolated from the decayed concrete a number of strains of a bacillus, and attributes to it a large share of the process of oxidation to sulphuric acid. The organism for which the somewhat fearsome name *Thiobacillus concretivorus* is proposed, is strictly autotrophic, readily converts free sulphur to sulphuric acid but cannot utilize sulphates, sulphides, or hydrogen sulphide. It grows best at pH 4.0, but can grow and produce acid at any pH less than 6.0. All the strains are completely inhibited at pH 6.5. Tolerance of the bacillus to acid is remarkable, cultures of two of the strains, incubated for 80 days, producing acidity equivalent to 10% sulphuric acid, and three other strains still producing acid in a medium already containing 8% sulphuric acid. From the numbers of bacilli isolated from typical specimens of decayed concrete, and from the ability of the organism to corrode cement mortar in an atmosphere similar to that of a sewer, Parker concludes that *T. concretivorus* is responsible for the final active stage of corrosion of concrete. No explanation, however, is given of the changes which take place during the preliminary period of very slow corrosion. It is not yet clear how hydrogen sulphide is oxidized to free sulphur, which the bacillus requires for growth. Also, concrete is distinctly alkaline, and we do not know as yet by what agencies the pH is brought below the point at which *T. concretivorus* can take control. It is important that the whole process be understood, and it is hoped that the work will continue with a view to clearing up the outstanding points.

RHEUMATISM AND NEUROSIS

In recent years there has been a welcome tendency to more precise analysis of the symptoms of chronic rheumatism. It is not enough nowadays to diagnose rheumatism of the shoulder. A painful shoulder may be due to osteo-arthritis of the acromio-clavicular joint, a subacromial bursitis, prolapse of a cervical disk, fibrositis of the articular capsule of the shoulder-joint, or hysteria, and each of these will require different treatment. It is generally agreed that lumbago and sciatica are only symptomatic diagnoses, though they are real enough to the patient, and the terms fibrositis and fibrous nodule themselves have come under revision. Nevertheless, a great deal of water will have to flow under the bridges before diagnosis in terms of exact pathology will generally be feasible in the non-articular forms of rheumatism. The diagnostician who used the American Medical Association's Classified Nomenclature, in which every disease is presumed to have a local habitation and a name, will often find himself in difficulties in setting down the anatomical position and pathological nature of the lesion in a patient with non-articular rheumatism. The dilemma is stimulating, if humiliating, and few clinicians would doubt that in cases properly diagnosed as fibrositis or sciatica a local tissue change is present. Its effects may be modified by the state of the psyche, but it is not primarily psychogenic in origin. We are beginning to get a clearer picture of the nature and reference of the tissue changes as a result of the work of Copeman and Ackerman¹ on the fibrous nodule or fatty hernia of the back, F. A. Elliott² on the trigger areas, and Lewis and Kellgren³ on the basic qualities of somatic pain.

It has long been known that patients with neurasthenia suffer from "rheumatic" pains. We may be forgiven for using the comprehensive term neurasthenia, if only to recall Allbutt's⁴ description of the rheumatic pains and backache in this disorder. Many patients with this complaint have come under observation in the armed Forces during the war, and it is not surprising that they have at first been diagnosed as having fibrositis and treated for that. An excellent description is given by Flind and Barber,⁵ who point out that the so-called rheumatism consists of indefinite pains, rarely limited to the joints or any one region of the body. There is no swelling of the joints, and there are no sharply localized fibrositic nodules or trigger areas, though the patient may react excessively to deep palpation of the muscles. Diagnosis is not difficult if the patient is considered as a whole and attention is not too closely focused on the locomotor system. There is usually a personal and family history of neurosis and morbid fears about health, and other nervous symptoms are present such as feelings of exhaustion, pain behind the eyes, tremors, dizziness, blacking out, insomnia, headaches, and dyspepsia. Several explanations have been given of the mechanism of the so-called rheumatic pains in neurasthenia. Aggressive feelings which have been inhibited may find expression in muscular tensions—the cramped muscle reflects the cramped mind. If it is assumed that the pains are conversion symptoms, their situation may be explained by a local predisposition in the shape of a subclinical fibrositis; or it may be symbolic, representing inward feelings of resistance, obstinacy, and resentment. There is a slight flavour of the hothouse about these views, and the clinician may well turn back to Allbutt with his ideas of postural fatigue and lowering of the nervous threshold.

The complaint is obviously similar to the inefficiency of the respiratory musculature and the precordial pain which are characteristic of effort syndrome. The same type of patient is affected, and it is probable that experiment would show the same poor response to exercise and premature exhaustion as has been observed in effort syndrome.⁶ It is misleading to include these cases under the heading of rheumatism, for the word rheumatism by derivation implies the defluxion of a morbid humour to the part—that is to say, a local tissue change. They should be diagnosed in terms of psychiatry or constitutional pathology. There is undoubtedly a psychosomatic approach to rheumatism, but it will not be made easier by confusing rheumatism with neurasthenia.

THE BRITISH LEGION'S WORK

The report of the British Legion for 1944-5 is issued from Cardigan House, Richmond, Surrey. Membership grew during the year, and men and women who served during the war are joining the Legion in considerable numbers. More and more it has been consulted on everything connected with rehabilitation and resettlement, not only by Government Departments concerned but by a number of voluntary organizations either directly or indirectly interested in these problems; co-operation with other bodies has been a notable feature of the year's activities. The Council views with great concern the housing situation as it affects men and women leaving the Forces. Re-establishment of family life, in the Legion's view, not only is a problem of major importance for ex-Service families themselves but also holds out the gravest possibilities for the country if neglect continues. The annual conference proclaimed its fears for a situation which might well arise from the consequences of delay and ineffectiveness in dealing with this most vital matter. Among many other branches of work the Legion's Employment Bureau has continued to function during the year, and the number of placings was 9,530. On March 21, 1945, the Queen opened the British Legion Sanatorium at Nayland. Five months before then the medical director, Dr. J. B. McDougall, was seconded to U.N.R.R.A., but the B.L. village was fortunate in having on its honorary consulting staff Dr. F. R. G. Heal who undertook during Dr. McDougall's absence to act a honorary consulting medical director, and during the year he frequently visited Nayland, and Preston Hall, and Douglas House, Bournemouth. An important development on the medical side of the village scheme has been the setting up of a committee of consultants composed of physicians and surgeons who advise the council on management on medical matters in the administration of the three institutions. The council puts on record its appreciation of the valuable work done by members of the profession in connexion with the various cases they have to be dealt with.

The next session of the General Medical Council will begin on Tuesday, Feb. 12, at 2 p.m., when the President Sir Herbert Eason, will take the chair.

Dr. H. E. Magee will deliver the Milroy Lectures on Tuesday, Feb. 12, and Thursday, Feb. 14, at 5 p.m. at the Royal College of Physicians, Pall Mall East. Subject: "Application of Nutrition to Public Health—Some Lessons of the War."

MEDICAL EXPERIENCES IN SIAM

The following is an abstract of the experiences recorded by Capt S S PAVILLARD Medical Officer of 'D Battalion of 650 prisoners of war sent from Changi near Singapore to Siam by the Japanese as a working party. The period covered is from April 1942 to Aug 1945

The march of 15 miles from Changi to Havelock Road Singapore proved very exhausting, the men carried all their kit and had for the previous three months been on a starvation diet. Many fell out of the line of march suffering from "black-out" and heat exhaustion. On our arrival at Havelock Road Camp we found that conditions were deplorable in every respect. The complete absence of latrines was responsible for the ground being fouled and for the outbreak of bacillary dysentery. Washing and cooking facilities were totally inadequate and the whole camp area had been used as a refuse dump by the local Asiatic community. The morning after our arrival one of the men was found to have died during the night from cardiac beriberi, which no doubt had been precipitated by the gruelling ordeal of the previous day.

Arrangements were immediately made to clean up the camp, but the men were still grossly overcrowded in the bug and louse infected huts. Consequently many slept in the open. The men were worked as coolies and although the rations showed some improvement on Changi standards, this was not sufficient to prevent the widespread outbreak of deficiency diseases, particularly beriberi and pellagra. These conditions prevailed throughout our captivity, and the men lived on the threshold of avitaminosis. Any great exertion or fatigue invariably caused an outbreak of beriberi and pellagra. The men were "paid" at the rate of 10 cents a day, representing approximately 1s 6d per week, and out of this sum essentials such as soap had to be bought.

The most prevalent diseases were beriberi, pellagra and bacillary and amoebic dysentery. Practically the whole camp suffered from scrofula dermatitis (B deficiency). This caused great irritation and resulted in a weeping dermatitis. Diphtheria was prevalent at the time and many men contracted diphtheritic scrofula. We had brought a very limited supply of drugs from Changi which were soon exhausted. The Japanese gave us no drugs whatever, but at our request allowed us to make purchases locally.

On Oct 12 we left Havelock Road, and marched to Singapore Station carrying all our kit. Here we entrained in covered goods wagons—32 men to a truck, the floor area of which was about 18 ft by 7 ft (5.5 by 2.15 m). There were not even the most primitive sanitary arrangements on the train and on arrival at Seremban, our first stop after a journey lasting some 13 hours, we must have provided excellent entertainment for the local populace. This exposure of our men to ridicule was repeated at every halt on our journey through Malaya and Siam. There was a great shortage of drinking water, and washing facilities were non-existent.

On our arrival at Ban Pong on Oct 17 we were marched to a camp sited in a paddy field which was completely under water. This was the first opportunity I had had to hold proper sick parades. There were many cases of diarrhoea and dysentery and one case of diphtheria. The hut that went by the name of hospital was flooded to a depth of 2 ft (61 cm) and was grossly overcrowded, the patients lying on bamboo platforms 2 to 3 in (5 to 7.5 cm) above the water. The water was full of mosquito larvae and there were many cases of malaria. As a result of my sick parade 20 men were left behind when, next day, we started on our long march up-country.

Throughout our captivity everything had to be carried on our backs. Therefore our drugs were split up into small parcels and carried by volunteers. The experience of later parties proved the wisdom of this method, for in the majority of cases parties left their medical supplies at Ban Pong on the understanding that the Japs would forward them by river transport. Of course the supplies were stolen by the Japs and the parties never saw them again. We took two days to march along the made road from Ban Pong to Kamburi (some 39 kilometres). During the march many men suffered from heat exhaustion and stomach cramps due to loss of salt by sweating. Some became so exhausted that I ordered them to fall out, they were collected into groups and were later picked up by Japanese lorries. During the march the Thais gave us fruit, salt, aspirins, and quinine. The only water available was from roadside wells and could not be boiled or chlorinated. During later stages of our march through the jungle men drank from stagnant pools which were often full of mosquito larvae.

On our first night's stop and again the second night the men were in a very exhausted condition and a great number were suffering from foot blisters. My orderlies and I were dressing feet until 2 a.m. The Japanese tried to force us to march again the following day, but when I repeatedly pointed out that some 250 men were quite incapable of moving they dropped their bullying tactics and the next day we rested. In view of the physical strain which the men had undergone, I decided thoroughly to examine every one. Many complained of tightness of the chest and difficulty in breathing, and, on

auscultation, tachycardia and extrasystoles were found. As a result I reported to the Japs that 150 men would still be unable to continue the march the following day. This report brought forth the usual tirade and bullying attitude, but I pointed out that any delay would be the direct responsibility of the Jap commander and once again he climbed down. The 150 men remained in Kamburi and rejoined us some time later at Wampo having made the journey up river in barges. It is of interest to note that the average age of the men was 35 years and the average time of residence in the East 11 years.

The next day we marched through flooded paddy fields before reaching the jungle. The Japs often lost the way, and this meant that several times we retraced our steps for miles, weary miles. At that night's stop at the village of Rajah we found cover for only 100. The remainder slept out and there was heavy rain during the night. There was no provision for feeding except a supply of uncooked rice, and an adequate supply of drinking water was not forthcoming. We had to collect firewood and boiled the rice which made the first meal since 9 o'clock that morning. After the usual argument we rested the next day, and when we resumed the march 7 men were left behind owing to sickness, they, too, joined us later on. This day's rest did much to restore the men's spirits and they were able to wash themselves and their clothes for the first time since leaving Singapore.

The following day we covered 20 kilometres to the river-crossing at Tardau. The route lay through thick jungle and we used footpaths and bullock-cart tracks. We were up to the knees in mud and many men lost the soles of their boots. This day's march was the worst we had experienced, but the men's spirits remained high. Many of the stronger men helped their comrades and carried their kit. On arrival at the river-crossing we were met by a fanatical Jap officer who, armed with a heavy bamboo stick (with which he satisfied his sadism), herded us into parties of 40 to cross the river in barges.

Conditions at Wampo Camp

A day later we arrived at Tarsau, whence we were sent down river by barge to Wampo some 30 kilometres away. Wampo was to be our home for the next 7 months. Our task was to build a section of railway 12 kilometres long, with a viaduct and bridge at each end. Much of the track had to be hewn out of solid rock. The camp consisted of two huts apart from Jap accommodation. Therefore some 67% of the men were forced to sleep in the open until more jungle had been cleared and other huts built. The camp eventually held 1,500 men. The food consisted of plain boiled rice three times a day, there was no tea, sugar, or salt. Many men fainted on parade and at work. "Black-outs" were very common, and occurred when one stood up quickly after stooping or sitting. Gastro-intestinal disorders were on the increase as was malaria. We managed to obtain two tents, onto which we crowded 50 of the worst sick in order to protect them from the rain. We were unable to obtain prophylactic quinine and had the greatest difficulty in getting it for specific treatment. The Japs eventually supplied 9 g (0.5 g) per day for five days as a full course, consequently relapses were frequent.

About a week after our arrival at Wampo the first death occurred. The man was a lance-corporal (?) of the 2nd Gordon Highlanders, and died of acute bacillary and, I suspect, amoebic dysentery followed by a perforated bowel.

On Oct 28 Capt Richardson, R.A.M.C., reported a case of appendix abscess. The man's temperature and pulse were rising rapidly, and it was considered necessary to operate and drain. We had of course no operating room but constructed a bamboo table in the M.I. room. We had practically no surgical instruments at all (I had been unable to acquire any in Singapore). In fact, we had only three pairs of artery forceps, one pair of scissors (rusty), a few surgical needles and some catgut. Worse of all, we had no knife. I decided to use a cut-throat razor, and I must admit that it was one of the sharpest instruments I have ever employed. As an anaesthetic we used chloroform. Before the start of the operation the Jap M.O. arrived from Tarsau, and I asked him if he would assist me or give the anaesthetic. His answer was a silly grin accompanied by the remark that he would just look on. Pte Riley, R.A.M.C., administered the anaesthetic while Capt Richardson assisted. The abscess was located and drained.

The camp was now taking shape, and we had built a hospital to accommodate 100 men, we had in addition a dysentery wing. Felling 50 jungle-clearing progressed, and the hut accommodation increased daily. The sanitary arrangements rapidly improved, and this did much to reduce the incidence of dysentery. We were also one of the first camps to have meat, which we bought locally from the Thais. This amount was small, but was privately supplemented with lizards and snakes. These were quite appetizing, and python steaks tasted rather like fishy chicken. Tegons were also good, but difficult to catch.

As already stated we were 1,500 strong, and after 7 months of hard manual labour we had lost only 15 men. Three of these deaths

were due to drowning. Other and less fortunate camps were at this time losing anything from 60 to 120 men per month. In due course I was allowed to set off down-river with the Jap camp commandant and succeeded in buying \$800 worth of drugs, including 100 kilogrammes of peanuts. Prices were very high: 1 tablet of sulphapyridine cost \$1 (in three years it rose to \$35), and emetine cost \$12 per grain (65 mg.), rising in three years to \$100. The arrival of these drugs did much to boost morale. The camp was now finished and parties started clearing jungle for the railway.

Diseases prevalent at Wampo

A month after our arrival at Wampo the most common diseases were: malaria (daily on the increase), beriberi (neuritic and oedematous), tropical ulcers, amoebic dysentery (bacillary dysentery had shown marked decrease), diphtheria, pellagra (early signs—i.e., stomatitis, glossitis, and skin rash). Among these were some interesting clinical cases, but owing to lack of paper it was impossible to keep notes. We had not enough specific drugs to treat all cases; therefore these had to be withheld until the patient's condition was desperate. It was often a very difficult decision to know when, and to whom, to give specific drugs, as so many cases were in need of them. However, by cutting down the recognized dosage it was often possible to tide a patient over the acute phase of his disease, though convalescence was usually prolonged.

In amoebic dysentery it was found that 2 gr. (0.13 g.) of emetine would convert an acute E.H. to the more chronic stage of E.H. cysts. This often brought about a cessation of blood and mucus and a rapid improvement in the patient's health. We had no microscope at Wampo, and diagnosis depended on clinical findings.

The diphtheria patients often developed pharyngeal paralysis, and whenever they swallowed any fluid it regurgitated up the nose. I cannot help feeling that there was mixed infection with Vincent's angina, and as I had at the time some N.A.B. a few patients were given 0.45 g. intravenously, with remarkable results; for the membrane disappeared and temperature dropped to normal in a very short period. Yet had a case been only Vincent's angina one would not have expected pharyngeal paralysis to develop; but in most cases, whether they received N.A.B. or not, it did. The Japs would give us no antidiphtheritic serum. In spite of that out of 20 diphtheria cases we lost only 2.

The work on the cliff face was proceeding slowly and the Japs brought in a further 2,000 P.O.W.s. This marked the beginning of what was called "the speedo period." Everything was done at the double; the weekly half-day was abolished, and the men had no chance to wash or air their clothes. Scabies, ringworm, and other skin conditions were rife; the huts became a living mass of bugs and lice. Tropical typhus, beriberi, pellagra, malaria, dysenteries, and tropical ulcers were all on the increase. The hospital was full, and sick personnel had to work as orderlies. The Japs now started paying officers \$20 a month, half of which went towards buying extra food for the hospital—eggs, etc. The men, who were paid 10 to 20 cents a day according to rank, also contributed a proportion of their money. On my original trip to Kamburi I had bought some sacks of rice-polishings, and on our advice the Japs eventually included these in the rations. We were able to give each man 1/4 pint (14.2 c.cm.) daily, and there was a marked decrease in the incidence of beriberi.

Outbreak of Cholera

We started up-country at the end of April, 1943, "D" Bn. leaving last. After marching 40 kilometres we arrived at our next camp, Tonchan South, and here we first encountered cholera. Information was received that it had broken out at Tak anum, some 100 kilometres further up. Full cholera precautions were immediately taken and lectures given, so that when the infection started, as it did on June 8, the men were well acquainted with all its manifestations and there was no panic. I am glad to be able to say that, although "D" Bn. was at different times in three of the worst cholera areas, we lost only 7 men. Considering that some battalions lost up to 50% of their strength, I cannot help feeling that many contracted the disease through sheer ignorance of elementary hygienic principles. Not only was this apparent with cholera, but with dysentery, malaria, etc., the average O.R.'s sense of hygiene was very poor. I was fortunate in having with me in "D" Bn. educated men—lawyers, chartered accountants, and business men—who made up 70% of our strength, and they could be trusted to carry out advice given.

We found that the camp at Tonchan South was grossly overcrowded, and men were sleeping in leaky tents. Sanitary arrangements were totally inadequate, and parties were still arriving. In all there were 3,000 P.O.W.s and about 2,000 Asiatic labourers in an area of less than half a square mile (1.3 sq. km.). Soon after our arrival the Jap camp commandant (S/Sgt. Hirumatz) asked me why there was so much sickness. I urged him to let us have a larger sanitary squad, as we were allowed only one sanitary orderly per 500 men. I also warned him of the danger of cholera breaking out, particu-

larly as the coolie labour force washed in the only stream at a point above that at which we were able to draw our water. He would do nothing about it, and blamed the men for contracting diseases, saying that they did not wear shirts at night (the majority had none), but wore G-strings. Three days later Hirumatz sent for me, and to my joy was in the throes of a malarial rigor. I passed the obvious comment, but he saw no humour in the situation and wanted to be treated. I may add that except at Tarsau there was no Japanese medical officer at any camp, and consequently we had to treat Japs and Koreans. To have refused would merely have brought serious repercussions on our own sick. Only very seldom did the Japs contribute small amounts of their very inferior drugs.

Before leaving Wampo I had asked for anticholera vaccine and had been refused. However, on April 7 I walked to Tarsau and succeeded in getting some. On the following day, back at Tonchan South, I was asked to see a case, and it was the perfect textbook example. This case was reported at once to the Jap commandant, who ordered us to move the man to Tarsau. We argued that such a move would only help to spread the disease. He threatened us, but, fortunately for the men of Tarsau, three more cases were diagnosed within an hour, and Hirumatz, by now thoroughly frightened, sent for the Jap M.O. from Tarsau. On his arrival the M.O. agreed with us, and we made a small clearing in the jungle, where we pitched the one (leaky) tent available. The men were taken there on improvised stretchers (a rice sack slung on two bamboo poles). By night we had 10 cases; some had died. We applied for more tents, larger parties for clearing and grave-digging, but all our requests were refused. The camp commandant said that nothing could be done, and the men must be allowed to die. We were therefore forced to take tents from fit men (leaving them in the open) and make up grave-digging parties with officers and the sick. Deaths were occurring at such a rate that we had to dig pits within 30 feet (9.14 m.) of the tents, having too few men to clear jungle.

The coolies were dying like flies, and many fled only to die in the jungle. Our working parties were constantly finding and burying the bodies while going to and from work. The Japs moved the coolie cholera tent next to ours; these coolies had no doctors or orderlies, and were allowed neither food nor water. Their cries for water were pitiful to hear. However, our orderlies passed both food and water to them without difficulty. The Jap guards were so terror-stricken as to be useless. Three times a day a Jap orderly, with two of our sick men, went to the coolie tent and ordered the removal of the dead and dying. These were dumped into the pit, both dead and alive, along with our dead. The pit was then lightly covered with earth, and the stench of putrefaction was terrible.

Somo six weeks before the outbreak I had constructed, as a precaution, a small plant for distilling water for intravenous salines. It was a very primitive affair, the condenser being a coiled rubber tube inside a hollow bamboo in which cold water was circulated. The boiler was a 4-gallon keosene can. Unfortunately it exploded one day, scalding the operator; but it was soon replaced. Within 24 hours of the outbreak we were able to give intravenous salines. The plant was producing 40 pints (22.7 l.) daily, and eventually double that figure. The giving bottle was a jam-jar connected to a needle by a rubber tube. It was almost always necessary to cut down to the vein to insert the needle, as the vein was completely collapsed. We had no local analgesic to inject around the skin before cutting, but fortunately most of the men were insensitive to pain. In addition to salines patients were given potassium permanganate 3 gr. (0.2 g) wrapped in a cigarette paper, and swallowed every 1/4-hour. Selected cases were given sulphapyridine with what appeared to be satisfactory results.

Conditions Up-country

On July 1, 1943, 550 men were ordered up to the dreaded Kayu No. 3 camp, where they were to work on a cutting 90 ft. (27.4 m) deep through solid rock. This place was known as Hell-fire Corner. Conditions in the Kayu area were truly appalling; at the river camp there were some 500 living skeletons barely capable of movement. They were awaiting evacuation to Tarsau, and were all suffering from the usual beriberi, malaria, dysentery, pellagra, and tropical ulcers. During the previous three months there had been 100 deaths each month. Our camp was to be in this Kayu 3 area, and sanitary conditions there were a nightmare. We cleared the camp area in torrential rain and erected our leaky tents.

It will be indicative of conditions to outline the course of the stream from which we drew water for all purposes. At its head it ran through a camp of 500 men of "H" Force; they had already lost 220 men from cholera. It then ran through a coolie camp where also there was cholera. From here it ran along the side of a track and was used as a watering-place for elephants. It then entered the original Kayu 3 Camp, containing 500 men; 35 had been lost here owing to cholera. Their cholera compound was on the opposite side of the stream to the camp, therefore anyone leaving the compound for the camp had to walk through the stream in heavily contaminated boots. The Japanese had strictly and vindictively forbidden the construction of a bridge. Three days later one of our cooks who was washing sweet potatoes in the stream absent-mindedly

chewed a piece, he developed cholera in the morning and was dead in the evening.

We were in the Kavu area for three weeks, during which time we had 7 cholera cases, of which 4 recovered. It is not surprising that after this period, when men went to work at 8 a.m. and returned at 5 o'clock the following morning we had 250 heavy sick out of our total of 550. Another party of 500 also had 250 heavy sick, and this party moved into Kayu I where a hospital and doctors were available but no drugs. The 'fit' men of "D" and "F" Bns. were moved up to Hintoek for further work and I went with the sick to Tonchan Main Camp whence I hoped to evacuate the worst cases to Tarsau Base Hospital. I myself was at the time suffering from amoebic dysentery, the last emetine had been used on an acute case some weeks before.

It was now that Hirumatz repeated the behaviour which we had already suffered from at Tonchan South. It was his habit to parade the sick in all kinds of weather and at any time of the day or night. He was under the delusion that he could find fit men among the sick. He frequently accused men of malingering and administered terrible beatings.

On Sept. 3, 1943, I moved north to Kinsayok with 50 of my 250 heavy sick who had been refused evacuation down river. A few days before leaving I received a consignment of drugs from the Swiss consul via Mr. Pong. The money to buy these drugs in the black market in Bangkok was subscribed by the European residents among whom were many Germans and Italians. Conditions were better than anything we had known since Wampo, but they were marred by Sgt. Okado, the Jap medical sergeant. This man, known as Dr. Death, repeatedly beat up the sick and also the doctors, whom he said were responsible for the numbers of sick.

On Jan. 14, 1944, a party of 500 men, mostly "B" and "D" and "F" Bns., was sent to a small camp on the river bank in order to haul barges through the rapids. I went with them as M.O. The work was easy, but we had practically 100% of malaria. After six weeks these men were sent down to Tarsau and I was ordered back to Kinsayok. On my arrival there I found the camp overrun by rats, many of which were dying from what the Japs said was bubonic plague. The whole camp was turned out to kill rats, and in six weeks we destroyed 10,000. Typhus had now started and we had many cases.

On April 1 I went down with tropical typhus, and have never felt so ill, there were several other cases, and we were moved under an improvised awning. The heat at this time was intolerable—in fact, so bad that clinical thermometers registered 104° F. throughout the day. The only way to ascertain a patient's temperature was to take it first thing in the morning or last thing at night. For 17 days I had fever, and this was followed by malaria. I had lost so much weight that I was forced to sell my fountain pen to the Thais for which I got \$25, and used it to buy eggs. Throughout our captivity almost everyone was forced at one time or another to sell personal valuables in order to supplement rations. A great deal of Japanese equipment (changkols, shovels, axe heads, etc.) was also sold. The risk was heavy, as penalties were exacted with animal ferocity.

In May and June large parties of heavy sick arrived from Tarsau and Chungkai, bringing fortunately, a number of doctors with them. On June 6 we received the first consignment of food and drugs from America. Much of the food and a large proportion of the drugs were appropriated by the Japs. Even so, what we received was a godsend. As an indication of the scale of Japanese thieving, we received one parcel for every 64 men, although we knew that one food parcel per man had arrived.

Month after month of the appalling conditions during which time men were not allowed to report sick at an early stage of their diseases, rendered their ultimate cure difficult or impossible even if specific drugs were available. When men were eventually allowed to report sick the clinical picture was usually complicated by the fact that the patients were suffering from several diseases at the same time. Furthermore, they had lost interest in things around them, and the will to live. I have on many occasions argued and reasoned with the unfortunate men, but they were exhausted beyond the limits of human endurance. Even to-day we are still fighting to save some of the pitiful human wrecks who have survived the last three years.

At Christmas we were allowed a pantomime. It was a great show, and cheered everyone up. We heard that officers and men were to be separated, the men felt this keenly, for we had worked side by side for the past 3 years, and the officers had always stood between the Japs and their men. On one occasion Major Clark in the course of an argument with the Japs was struck heavily and his ear drum was ruptured, this injury gave him much trouble.

On May 12, 1945, we started our journey to Pratchina, 110 kilo metres the other side of Bangkok. We travelled as far as Non Pladock in open trucks in very heavy rain. At Non Pladock, as usual, no arrangements had been made. We spent the night in two

semi-collapsed huts which had previously been used by coolie labour. The huts were indescribably filthy.

On the 14th, after crossing the river by barges, we waited four hours in blustering sun (most men had no shirts) for the Bangkok train to arrive. The river water was too dirty to drink, so we chlorinated water from adjacent paddy fields. At 1 p.m. a meal was brought to us from a near-by P.O.W. camp. This was to be our only meal until we reached Bangkok Docks the next morning.

At 6 p.m. we arrived at Bangkok goods station which had been heavily blasted by our bombers. In a few sheds left standing were Jap fighting troops on their way to Burma. The whole area was full of bombs, ammunition, mortars, etc. We embarked on barges at 10 o'clock and made a 7-hour trip down the river to Bangkok Docks and prayed there would not be an air raid. This trip was keeping with all journeys organized by the Japs—extremely uncomfortable, there were 50 men per small barge. We arrived at about dawn and had at once to unload the junk which the Japs seem to find indispensable on any move (wood, petrol, some rice, etc.). We finished this job by 9 o'clock and were allowed 20 minutes for a meal which was provided. Immediately afterwards the men were split into working parties and sent to construct emplacements and defences of all kinds in the dock area and in Bangkok. I had 70 sick by this time, but the Japs would allow only 40, so I had to pick out the 50 worst cases.

Early in July we received a small consignment of American Ped Cross drugs (our second and last during our captivity). After the armistice had been signed we discovered that the Japs had been withholding 35 cases of drugs and hundreds of blankets.

Conclusion

At long last the signs that the end was near became evident. On Aug. 16 we noticed Japanese troops burning papers, and in the afternoon there was a parade of their camp staff. When the parade was over some Korean guards signalled across the barbed wire the information that the war was finished.

As an indication of the incidence of sickness among P.O.W.s it is of interest to note that during the period of our captivity I saw an average of 120 cases a day, while at Kavu this figure rose to 400 a day.

Our evacuation to Bangkok was delayed by the arrival of 450 P.O.W.s who had been in contact with smallpox. These men had been marching since June and had covered 600 kilometres.

On Sept. 8 Lady Louis Mountbatten visited the camp and shook most of us by the hand. She was the first white woman we had seen for 3½ years.

HOSPITAL SERVICES: FUTURE PATTERN

THE MIDLANDS AND YORKSHIRE

In 1941 the then Minister of Health initiated a survey of hospital services, dividing England and Wales into ten areas for the purpose, and appointing, himself in some areas and the Nuffield Provincial Hospitals Trust in others, persons experienced in the clinical or administrative work of hospitals as surveying officers. The reports and recommendations of these officers are now being issued. Each report makes a large Blue Book. The teams of surveyors approached their task in different ways, some dealing with each hospital of the area in turn, others with districts and groups of hospitals or with the different branches of hospital service. The result is a Domestic survey of a scale and completeness never before attempted. The survey of the London Region was reviewed in the *British Medical Journal* of July 14, 1945 (p. 56). Below is a summary of the surveys for the West and East Midlands and Yorkshire.*

WEST MIDLANDS AREA

This survey was undertaken by Mr. J. B. Hunter, F.R.C.S., Dr. R. Veitch Clark, and Sir Ernest Hart. The area covered includes the geographical counties of Stafford, Warwick, Shropshire, Worcester, Hereford, and Northampton with Birmingham, with its million population, dominating the larger part.

Desire for Co-ordination

The surveyors have been impressed in practically every part of the region with the desire for co-operation between the rate-supported and the voluntary hospitals. Any difficulties have been "largely psychological on both sides." Action mon-

* H.M. Stationery Office. West Midlands Area, 5s. net, Sheffield and East Midlands, 7s. 6d. net, Yorkshire, 5s. net.

likely to be profitable would be: (a) division of functions between the two hospitals in each locality so that both undertook general medicine and surgery and allocated special departments between themselves, instead of both running smaller units; and (b) attachment of a single group of specialists to the staffs of both hospitals. Cottage hospitals are considered to be a necessary part of any organized hospital plan, but they should not assume the functions of a general hospital; they are peripheral units in any district served by a general hospital at the centre.

In each hospital district there should be a range of consultants adequately covering general medicine and surgery and obstetrics and gynaecology, as well as the principal specialties. At present the number of consultants is limited by the economics of the area. If there is no living to be made by consulting work then "full" specialists are not available for the staff of the hospital, and committees of management have to get along with general practitioners of the immediate neighbourhood.

"In the past the tendency has been for the general practitioner gradually to drift into surgery, or whatever branch of medicine he is most interested in, and to do this as an offshoot from his general practice; he may be entirely self-taught and without proper training for the particular branch he chooses. . . . The surveyors are of opinion that this is not the right procedure. They feel that hospital authorities should be in a position to pay a sufficient annual sum to enable consultants of approved training and ability to perform the work, and that such specialists should not have to be dependent on their private practice to enable them to live."

Having gone as far as this in areas concerning which a subsidy is found necessary to secure adequate specialist service, they feel bound to go on to affirm that all consultants should be paid for their hospital work.

The need for a complete change of outlook in the care of the chronic sick has impressed them. They recommend that no patient should be admitted directly to a "chronic" hospital; he should in the first instance be admitted to a general hospital for a thorough assessment of his case. Accommodation for the chronic sick should be planned on lines which will enable the patients not only to receive good medical and nursing care but to enjoy life so far as their faculties permit.

Birmingham and District

The following hospital districts for the West Midlands area are proposed:

Birmingham	Shrewsbury
Bromsgrove	Stafford
Coventry	Stoke
Dudley	Stourbridge
Hereford	Walsall
Kidderminster	Warwick and Leamington
Northampton	West Bromwich
Nuneaton	Wolverhampton
Rugby	Worcester

In Birmingham there is need for a new general hospital with out-patient department to serve as a district hospital for the northern and eastern boundaries of the city. Birmingham General Hospital, in its unrivalled position, should extend and improve its out-patient department and emergency services. The new Queen Elizabeth Hospital should be completed as planned to provide more general and surgical beds. Selly Oak should have the major out-patient department for the southern parts of the city.

It is felt that in any scheme for Warwickshire Coventry should play a larger part and serve as a major hospital centre for the districts in the north-east; with it the district hospitals of Nuneaton and Rugby should be associated. Two general hospitals are suggested, of not more than 700 "acute" beds, to serve Coventry and the surrounding zone, with the same specialist staff available to both. The staffing of the general and special departments of Coventry hospitals is considered to need strengthening. A main district hospital should be situated at Leamington or Warwick and linked with Birmingham for certain specialist needs. A new hospital at Sutton Coldfield to serve the residential fringe of Warwickshire east of Birmingham is also considered desirable.

A general hospital in Worcester is recommended for the service of the central and southern parts of that county. Worcester Royal (within whose walls the British Medical

Association was founded) would naturally fill the position if strengthened in staff and in certain physical resources. A general hospital is also needed in Bromsgrove to serve the north-east of the county; the "hatted" All Saints Hospital should meet the immediate need, and with certain modifications might meet the requirements of a long-term policy. Kidderminster General Hospital, strengthened in its medical staff and eventually rebuilt away from its present restricted site, would serve a district, and Corbett Hospital, Stourbridge, is well placed to serve a population of 120,000.

The Black Country

North Staffordshire was found to be practically self-contained in its general hospital provision. The two large general hospitals at Stoke are both well sited, and the co-ordination of their work and that of the orthopaedic hospital is for the moment more important than extensions, but in time such extensions must be made, and the work of these hospitals might well be supplemented by a recovery hospital outside. In Mid-Staffordshire Burton-on-Trent is a natural centre for a population of nearly 100,000, but there will have to be an increase of beds. Stafford should be the centre of a hospital district of some 180,000 population, but here again the general hospital would need extension to perhaps 400 beds. In South Staffordshire, Wolverhampton, Walsall, West Bromwich, and Dudley each possess one or more general hospitals serving their town and the surrounding area. These four towns are considered to be natural centres at which to locate general hospitals. Smethwick would be served by St. Chad's, Birmingham, and Hallam, West Bromwich.

The Rural Midlands

Shrewsbury is the natural centre for the hospital district of Shropshire. The Salop Royal Infirmary, the County Hospital, and the Eye, Ear, and Throat Hospital, with a total of 430 beds, will need to provide the hospital services for the district until substantial rebuilding can be undertaken, and it is thought that it should be possible to secure some of the advantages of a united hospital right away by appointing to the three a common medical staff. Wolverhampton would be the most convenient centre to provide for Shropshire most of the consultant and other services not available in Shrewsbury, and Shrewsbury should look to Birmingham for its university connexions and for the rarer forms of specialist service.

The main task in Herefordshire is to secure a co-ordinated general hospital service. One general hospital of economic size would serve the area. At present there are two in Hereford—one voluntary and the other local authority—with no tradition of co-ordination. The surveyors hold that there is no room in Herefordshire for two such hospitals, though the total number of beds is required. The clinical departments of both institutions should be regarded as complementary and the staffs built up as one team. This would be facilitated by an allocation of functions between the two hospitals. Hereford could look most conveniently to Birmingham and its medical school and associated general and special hospitals for scientific inspiration, general consultative help, and certain less frequent specialist services.

Northampton, in the view of the surveyors, should be the centre of an organized hospital district for its county, with the general hospital there associated more closely with the one at Kettering. The Northampton hospitals would need to be linked to a university medical centre for stimulus, exchange of medical personnel, and certain services such as thoracic and neurosurgery and some forms of radiotherapy. Hitherto Northamptonshire patients needing treatment at a major centre have usually gone to London, and the attraction of London with its numerous medical centres and large numbers of consultants is bound to continue. Nevertheless, London is overloaded, and it is desirable to relieve it of all those areas which can be advantageously linked up with other university centres. Therefore it is proposed that Northamptonshire should be associated with Oxford, notwithstanding difficult railway connexions.

SHEFFIELD AND EAST MIDLANDS AREA

The survey in this area was in the hands of Prof. L. G. Parsons, Dr. G. E. Godber, and Mr. S. Clayton Fryers. The last-named did not take part in the survey of Derbyshire and

Yorkshire because of the unwillingness of the local authorities in those areas to accept a lay survivor. The area includes seven counties and part of an eighth comprising a population of close on four millions. There are two teaching general hospitals, both of them in Sheffield and other hospitals, larger than the teaching ones which are recognized in their districts as consultative centres.

General Criticisms

A marked tendency to over-development of certain aspects of work is noted especially lavish expenditure on equipment in competition with neighbouring hospitals.

"Elaborate operating theatres are commonly found in small cottage hospitals even in those where operations are relatively infrequent and sometimes may be performed by unskilled hands. We have seen complicated and highly expensive equipment for the treatment of severe fractures duplicated in hospitals the work of which would be better restricted to simpler forms of treatment, leaving the patient with a slightly longer journey to a better-equipped hospital where complicated treatment can be undertaken under expert supervision. X-ray apparatus is usually found in cottage hospitals, although many have no visiting radiologist or even radiographer."

The effect of contributory schemes on the normal flow of patients is mentioned. In some areas the survivors were told that non-contributors might have less chance of admission to the only available suitable hospital than contributors whose need was less, also that some contributory schemes associated with particular hospitals are reluctant to allow a patient to go to another hospital even though he might benefit by the special treatment obtainable there, because such treatment would involve payment from contributory scheme funds. On staffing the comment is made that there seems to be a tendency for municipal hospitals to seek to stand alone and to provide much of their medical service by means of whole time staffs, thereby necessarily reducing the opportunities for developing experience in special lines of treatment. Hospitals for infectious diseases vary exceedingly, from excellently designed ones at Sheffield and Leicester to the worst parodies of hospitals which need not be named.

Comment is made on the lack of co-ordination between authorities, even within the same administrative county.

"An arbitrary line on the map often determines whether a patient shall have access to a well-staffed relatively modern hospital in a natural hospital centre or be sent some distance away to an unsatisfactory institution, whether the case be one of infectious disease, tuberculosis, maternity, or some chronic illness."

The bad results of strict adherence to local government boundaries are nowhere better exemplified than in Leicestershire and Nottinghamshire, where the respective counties and county boroughs have each erected good sanatoria, each pair being only five miles apart, instead of combining to produce more efficient and larger hospital units. The same lack of co-ordination exists in general hospital work. In some areas the voluntary hospitals are accustomed to transfer chronic cases to municipal hospitals and to have little other relation with them. This position of dumping ground is hotly resented by municipal hospitals, especially when they have developed into well equipped acute hospitals, but in justice to the voluntary hospitals it must be said that in many instances until comparatively recently they alone were equipped to deal with the acute sick. In no area is there a general pooling of facilities. Even the sharing of consultant staffs varies greatly in degree.

Inadequate Consultative Service

Another striking point brought out in the survey is the inadequate numbers of available consultants. In Sheffield the number of consultants is too small for the town itself. Nottingham, Leicester, Derby, and Doncaster have long been recognized as consultant centres and, especially in surgery, have staffs of considerable size, but in medicine the number of consultants has been relatively less developed. New members of staffs of the larger hospitals are often recruited from general practitioners and some are still in general practice. Lincoln and Grimsby are in an intermediate stage in the development from general practice to consultant staff, in some other areas, such as Barnsley, Stamford, Mansfield, Chesterfield and Boston only one man is engaged solely in consultant work. Certain

specialties have been slow in developing. Only one gynaecologist who restricts his practice to that specialty is to be found in the whole of Lincolnshire. Paediatrics is relatively inadequately covered, even in Sheffield. Dermatology has not been largely developed apart from general medicine. Neurosurgery has been slow, thoracic surgery has developed very little, and plastic surgery is not organized at all.

The survivors express themselves dissatisfied with the position which permits a medical superintendent of a municipal general hospital to try to combine the work of administrator and clinician of consultant standing. The clinician of consultant standing at the municipal hospital should have complete responsibility for the treatment of his patients, whether he is a whole time employee of the authority owning the hospital or a visiting consultant giving part of his time to the work.

They are equally emphatic about general practitioner surgeons.

"Although there are general practitioners who are really first-class surgeons, the existence of general practitioner surgeons as a class has grave drawbacks, and the hospital services should be planned to eliminate the need for them. The evolution of surgery has reached the point where it is impossible for a man to maintain a sufficiently high standard of technique unless he is constantly employing it just as general practice now requires a breadth of experience which the surgeon lacks."

The general practitioner surgeon is not confined to voluntary hospitals; he is also found in public assistance institutions. In some local authority hospitals the surgeon will tackle anything regardless of inexperience. The survivors add that these comments are not intended to be derogatory of the general practitioner but only of the system.

General Shortage of Beds

The survivors are satisfied that there is a general shortage of beds in the area. There are exceptions in certain special branches, as for example, in Sheffield, where there are sufficient beds for infectious diseases, but for the type of case requiring the facilities of a modern general hospital, whether for treatment or investigation, there is not enough accommodation anywhere. The deficiency is greatest in Doncaster, the West Riding, Lincolnshire, and Derbyshire. The total number of beds in the area is just over 20,000 and it is calculated that 12,000 more are needed, including 5,800 more "acute" beds.

The principles for the organization of hospital services which the survivors lay down may be briefly summarized as follows:

- (1) The whole region for general hospital services to be served by area consultant services based upon hospital centres.
- (2) Each hospital centre to have locally resident consultants, smaller associated centres to have part time visiting consultants.
- (3) Functional union of and common staff for all the hospitals in the centre.
- (4) Cottage hospitals to be associated with neighbouring hospital centres and to be provided with nursing facilities for the type of case which would normally remain in the charge of the patient's own general practitioner, but no provision to be made for surgical work save in exceptional conditions when transfer is impossible.
- (5) Special centres, preferably at medical schools, to provide the more highly specialized services, and their staffs to be available for consultation.

The Sheffield Centre

The survivors consider that there should be a functional union of hospitals in Sheffield, with complete pooling of resources, for the benefit of the city and the district around. The special hospitals should have a right to call in consultants of all types from the general. The union of the Royal Infirmary and the Royal Hospital should become effective even while the present separate buildings remain. The City Hospital should make use of a greater range of consultants from the area consultant staff. The most urgent need in Sheffield is for adequate sanatorium accommodation for tuberculosis; a new sanatorium should form part of the Sheffield centre. The Jessop Hospital should be developed to approximately 300 beds, providing the principal gynaecological consultant centre for the area. Rotherham notwithstanding its proximity to Sheffield should be developed as a hospital centre and the same is true of Barnsley and Doncaster. In Barnsley the service of local resident consultants should be provided, but some of the specialists should

also be attached to the Sheffield centre. Doncaster should be self-sufficient for ordinary specialties, but cannot afford to "export." Chesterfield should be associated with Sheffield and not with Derby, and itself be developed on similar lines to Barnsley and Rotherham. Derby must provide a hospital centre of considerable size. The first phase must again be a functional union of the various hospitals.

Nottingham, Lincoln, Leicester

Nottingham is an old-established consultant centre, but the number of consultants here again is much too small. "At least a 50% increase of staff all round is required." The number of beds available in Nottingham is more nearly adequate than in some other areas, but there is acute need for more maternity accommodation. The conception of one major hospital including both paediatric and gynaecological beds on the City Hospital site is attractive.

Lincolnshire is the least organized area in this region. The first requirement is the establishment in Lincoln of an adequate service of consultants, who must be subsidized because there will not be enough private practice to maintain the numbers. There will be work for two or three men in all the usual specialties. Grimsby, where existing services are handicapped by lack of beds, should also be a centre of great importance. A relatively inadequate centre is Boston, around which there is a considerable rural population. "If building for general hospital purposes is justifiable anywhere in the region immediately after the war it is at Boston."

Finally, Leicester, where there is a consultative centre of high local reputation and long history. It is proposed that there should be a major hospital centre at Leicester, with a satellite centre at Loughborough. There are not enough beds available at Leicester for the present population, and still fewer for the county, but the number is more nearly sufficient than in other large centres with which the surveyors have had to deal. The consultant staff of the Royal Infirmary should be increased by 50% as soon as possible, and there should be pooling of resources to give the consultants clinical responsibility for patients at the municipal hospitals.

YORKSHIRE AREA

The survey of the Yorkshire area was undertaken by Sir Herbert Eason, Dr. R. Veitch Clark, and Mr. W. H. Harper. The surveyors were informed that the municipal authorities at Bradford declined to be associated with the survey, and therefore they did not visit the Bradford municipal hospitals. The population of the area is nearly 3,000,000. Leeds is the only university town. The surveyors recommended five hospital divisions—Leeds, Bradford, Harrogate, York, and Hull and East Riding. They assess hospital need according to the following standards: Beds for acute cases 4 per 1,000 population; for chronic cases 2 per 1,000; for maternity cases 0.5 per 1,000; for tuberculosis 1 per 1,000; for infectious diseases 1 per 1,000. On this basis the deficiency of beds in the various centres is as follows:

Bradford	981	Hull and East Riding	1,310
Dewsbury	625	Leeds	1,459
Halifax	515	Wakefield	346
Harrogate	184	York	1,154
Huddersfield	478		

Postgraduate School Proposed

It is also the view of the surveyors that the number of trained and experienced specialists in the region is inadequate for the population to be served. The number of consultants and specialists not engaged in general practice is 124, and the number engaged in general practice 272. They consider it essential that a postgraduate school for the training of specialists should be established in this region, and recommend that at the earliest possible date the Royal Infirmary, Bradford, should become such a school and be in this respect a part of the medical faculty of Leeds University. Leeds should confine itself to undergraduate teaching.

On the question of co-operation between rate-supported and voluntary hospitals the surveyors urge the distribution between the hospitals of the area of the provision of special services which require highly trained staff and special and often expensive equipment. The impersonal issue of the allocation of special units should be first discussed, in their opinion, so as

to secure a broader and more temperate outlook on both sides. The provision of one special unit in a group of hospitals instead of special units in each hospital, all dealing with the same subject, is clearly not only economical in equipment and staffing but provides a much better service for the patients, and such an arrangement will make an easier approach to staffing problems later on. A useful example of an organization suitable for such co-operation is the Leeds Joint Hospitals Advisory Committee set up in 1936.

On the subject of good hospital provision the surveyors remark that the siting of hospitals in the more densely populated parts of the region has impressed them as a matter of very definite importance. They feel it to be to the advantage of the public that hospitals should not be established anew in fully built-up areas. New hospitals should be sited either on the periphery of towns or in the adjoining country. They further suggest that of thirty-nine infectious diseases hospitals in Yorkshire eighteen are of so little use that they might be dispensed with entirely. There is no reason, in their opinion, why any fever hospital should not serve the area measured by a radius of about fifteen miles. They add that no fever hospital should be without a resident medical officer. Nineteen small-pox hospitals in the area, most of which have been empty for fifteen or twenty years, are also recommended for elimination.

Better Planning for the Chronic Sick

Like the surveyors in other regions, Sir Herbert Eason and his colleagues urge that no person should be sent direct to a hospital for the chronic sick. Admission should be in the first place to a general hospital for the acute sick. They also make certain recommendations for the better planning of hospitals for the chronic sick. As for the staffing of such hospitals, while normal medical needs may be met by the routine visits of a local general practitioner, every such hospital should have directly on its staff at least a specialist physician and an orthopaedic surgeon visiting at reasonably frequent intervals. There should also be provision for social care.

There are twenty-one cottage hospitals in the region, and the surveyors were pleased and satisfied to find that these actually did fill the gap between domestic medical practice and the work of the larger hospitals. It is their experience that the cottage hospital does in practice confine itself to this sphere of activity, and they consider that it is difficult to over-estimate its value in the hospital scheme.

They recommend the setting up of children's hospitals in rural surroundings for Leeds, Bradford, Hull and East Riding, and York and Scarborough; also that there should be, wherever possible, one central orthopaedic department or hospital attached to the "key" or divisional general hospital and two long-stay hospitals in the open country working in close relationship with it. For general orthopaedic, fracture, and short-stay cases the Leeds area will require about 200 beds, Bradford 100 to 125, and Huddersfield, Halifax, and York 40 to 45 each. For the long-stay hospitals it is estimated that the beds required would be one in 5,000 of the population.

Short-term and Long-term Policy

The larger part of this survey is occupied with detailed comments on over 100 hospitals, beginning with the General Infirmary at Leeds, of which it is said that the practice of medicine and surgery is of the high standard characteristic of a university teaching hospital, but that if the medical school is to keep pace with the development of medicine and surgery very large extensions will be required to provide modern accommodation for certain specialties. The surveyors were not favourably impressed with the Leeds Maternity Hospital; the general effect produced was "rather depressing." They found certain of the arrangements unsatisfactory, but their comments imply no reflection on the standard of professional work, either of the medical or of the nursing staff. At St. James's Hospital, Leeds, the largest of the municipal hospitals, they found the health authority "very much alive to what a modern hospital should be."

In dealing with sanatoria they lay down the following principles:

(1) Institutional treatment of the tuberculous should form an integral part of the general hospital scheme, and sanatoria should be linked with key divisional hospitals.

(2) Sanatoria should also be linked to the dispensary and domiciliary service of the tuberculosis scheme

(3) Where practicable it would be advantageous that tuberculosis dispensaries be placed in general hospitals

(4) Non pulmonary forms of tuberculosis should be dealt with as part of the sections of orthopaedics and of paediatrics

(5) The major surgery of tuberculosis should be done at a thoracic surgery unit

Finally the surveyors indicate what in their view should be the short-term policy and the long term policy for each of the divisions. In the Hull and East Riding Division for example, under the short term policy, the Royal Infirmary, the Children's Hospital the Women's Hospital, and the municipal general hospitals should become component parts of one hospital centre, without necessarily losing their autonomy, and the emergency hospitals at Beverley and Driffield should be maintained in their present activity for the service of both the city and the county until the full hospital scheme has been put into operation. Under the long term policy it is suggested that to the three hospitals mentioned there should be added a fourth, situated somewhere in the county, to meet the deficiency in bed accommodation. In York again, under the short term policy, the format on of a key hospital centre by the existing county and city hospitals together with the emergency hospital at Nayburn, is recommended, the long term policy would necessitate the erection of an additional general hospital.

The surveys of the North Western area South Wales and Monmouthshire and Berkshire, Buckinghamshire and Oxfordshire will be reviewed in a later issue.

THE MEDICAL DEFENCE UNION

SIXTY YEARS OF SERVICE

The Medical Defence Union is celebrating its Diamond Jubilee and by a luncheon on Jan 15 it recalled its history and honoured the memory of the men who assured to the profession a service which has come to be recognized as essential to medical practice. The Union was incorporated on Oct 23, 1885, by a group of laymen under the leadership of C F Rideal, to provide doctors with an insurance against the risk of prosecution for malpractice, to meet attacks by libel or slander, and to suppress unfair competition by unregistered persons. On May 6, 1886, a Midlands Branch was formed at Birmingham under the chairmanship of the well known surgeon, Lawson Tait. Tait recognized the potential value of the Union to the profession and worked hard to set it on a firm foundation. He took the chair at the first annual meeting held in London and was there elected first president. A council composed of medical men was appointed, and early in 1888 new Articles of Association were adopted and the Union became an entirely medical organization.

Progress from Small Beginnings

During the first decade internal dissension and external rivalry made progress very slow. Nevertheless by the end of the century the main lines of current and future development had been defined and the Medical Defence Union had established itself as a permanent feature of British medical organization. The membership, which at the first annual meeting totalled 544, had grown to 4,604, and the reserve fund amounted to £7,637. The next 20 years saw a progressive rise of membership, at first somewhat slow, with a slight setback during the war of 1914-18, and after 1920, when the membership was 9,032 and the available funds £19,876, the Union made rapid headway, outstripping in a few years all its previous records. The membership to day approaches 30,000, and the available funds exceed £150,000. This remarkable growth and consolidation could have been secured only by the adoption of a policy and the pursuance of a procedure that met with acceptance from practitioners in all branches of the profession.

The content of medical defence has broadened with the extension of medical practice into new spheres of activity, and the Council of the Union finds more and more ways whereby it may serve its members. In addition to the individual medical defence of members involved in or threatened with legal actions, the assistance of members worried by medico legal difficulties, both great and small, in the course of their profession, and arbitration in disputes between members, the Union has developed the collective defence of the profession

in the medico legal sphere. Under this heading come the suppression of practice by unregistered persons, the reporting to the General Medical Council of practitioners conducting themselves in a manner alleged to be infamous in a professional sense, the interpretation of Acts of Parliament and official regulations, and advice on the medico-legal aspects of new methods and techniques in medical practice.

Of the men whose work for the M.D.U. and the profession are being remembered at the Diamond Jubilee, a few only can be mentioned. C F Rideal, originator of the idea of medical defence. Lawson Tait, first president, the line of secretaries—Leslie Phillip A G Bateman, James Neal, Robert Forbes—and Campbell Pope and Victor Jaynes, who gave honorary service, the early treasurers—Granville Bantock, J A Masters, and F J Wethered, the solicitor, W E Hempton, and his son, Oswald Hempton, and among those who served very long as members of Council, M Hallwright, M Arden Messiter, and W S A Griffith, the sole survivor of the pioneers of medical defence. It is fitting to mention also Victor Horsley, Charles Ballance, Herbert Waterhouse, and Eric Pearce Gould, who gave of their best in promoting the success of the M.D.U.

At the luncheon party last week in London the president Mr St J D Burton, F.R.C.S., took the chair, and gave a brief survey of the earlier years of the Union in acknowledging a toast proposed by Sir Alfred Webb Johnson, P.R.C.S., who had paid tribute to the valuable work done during 60 years not only for individual members but for the profession as a whole. With the approach of a new concept of civilian medical practice in the form of a National Health Service wider fields of activity may be open in which the help of the Council will be sought by members engaging in that service who need personal protection against attacks and guidance in the operation of multifarious regulations.

PHYSICAL EDUCATION IN INDUSTRY

At the annual general meeting of the Research Board for the Correlation of Medical Science and Physical Education on Jan 16, under the chairmanship of Dr Frank Howitt, a report, *Medical Science and Physical Education in Industry*, was approved for publication. It is complementary to the three part report on medical science and physical education in their relation to maternity and child welfare, education, and the Services published in 1945. This year's report covers certain aspects in industry, including nutrition and diet, job analysis, job specification, vocational selection, vocational guidance, recreation, occupational health services, rehabilitation of young persons in industry, women in industry.

Research Board's Recommendations

A number of recommendations are made by the Board, among which the following stand out as of special importance.

More co-ordination should be effected between organizations making a special study of, and advising on, job analysis, job specification, vocational selection, vocational guidance, and the advice of these bodies should be made more readily available to all types of firms.

The number of works medical officers and welfare workers should be increased. The co-operation of physical medicine specialists should be sought. Firms should also employ experts in physical education.

Suitable leaders of physical recreation should be trained. It is certain that with further training a number of ex-Service instructors would be suitable for this work. Although no guarantee of employment is expected, the appropriate Government Departments should encourage suitable firms to employ well trained men and women.

An industrial health service should be planned as an integral part of the National Health Service. It should be a co-operative undertaking with full support from both management and workers. The establishment of polyclinics within industry should be the subject of experiment. The education of management and workpeople on health problems in industry should be regarded as fundamental to any improvement in the health of our industrial population.

Medical officers and personnel officers should have facilities for undertaking research. University departments and other bodies should assist such men and women with their research problems.

Great stress is laid on accident prevention in sections of the report dealing with occupational health services and young people in industry, and in the section on rehabilitation the need for co-operation between all concerned with the treatment and

resettlement of substandard and injured men and women is strongly advised. The report reads:

"In any scheme of rehabilitation surgeons, physicians, psychiatrists, nurses, physiotherapists, physical educationists, education officers, almoners, welfare supervisors, Ministry officials, training centre authorities and instructors, trades union officials, employers, and the patients themselves should work together as a team. Closer liaison should be established between authorities responsible for medical rehabilitation and industrial resettlement."

The Research Board recommends plans for the adaptation of Service rehabilitation and physical development centres for civilian purposes, and emphasizes the need for establishing juvenile and industrial physical development centres on the lines found so successful in the Army physical development centres. It is very anxious that Service men and women doctors and physical training specialists should continue their work in research and treatment under civil conditions, and hopes that, where young people are concerned, the introduction of county colleges, made compulsory under the Education Act, may not be unduly delayed, and that these colleges should form a focal point for recreational and other activities. In the interests of the health of young workers the factory law relating to the hours of employment should be strictly enforced. Constant reiteration is made of the need for research and for closer liaison between industry, youth services, and voluntary organizations.

WAR MEMORIAL FOR NURSES AND MIDWIVES

A fund is being launched to provide a war memorial to the nurses and midwives of the British Empire who have given their lives in the war. The primary object of the fund, which is to be known as the British Empire Nurses War Memorial Fund, is to furnish a war memorial chapel in Westminster Abbey, which shall house a Roll of Honour of the dead. For this purpose £5,000 is required. A chapel has been allocated by the Dean and Chapter of the Abbey, and it is anticipated that the sum will be easily reached and passed, and that a substantial balance will remain to be used for the benefit of the nursing and midwifery professions in a way to be decided later. £50,000 is the minimum hoped for.

A distinguished Council of medical, nursing, and lay members has been gathered to serve the Fund, and it is hoped it will include representatives of the Dominions, the Colonies, and India. Medicine is represented on the Council by the Presidents of the Royal Colleges of Physicians, Surgeons, and Obstetricians, and the Chairman of the Central Midwives Board. Nursing representatives include the Matrons-in-Chief of the three Nursing Services of the Crown (the Royal Navy, Army, and Air Force), the Matron-in-Chief of Red Cross and St. John, the Chief Nursing Officers of the Ministries of Health and of Labour and the Department of Health for Scotland, and the Chairman of the General Nursing Council (who is also Matron of the Middlesex Hospital and the Matron-Elect of Guy's Hospital, London), and the Registrar of the General Nursing Council for Scotland.

The hon. secretary of the Fund is Miss J. Elise Gordon, M.A., Editor of the *Nursing Mirror*. The address is British Empire Nurses War Memorial Fund, Dotset House, Stamford Street, London, S.E.1, to which all gifts should be sent. Lloyds Bank are the Trustees, and all administrative expenses are being paid by the *Nursing Mirror*.

The Medical Missionary College at Vellore, South India, has recently been recognized as a constituent college of the University of Madras and is now able to train women students for the M.B., B.S. degree of that university. The College was founded in 1918 by the pioneer medical missionary of the American Arcot Mission (Dr. Ida S. Scudder) as a medical school for women. In 1938 Dr. T. S. S. ujan, the Minister of Health, abolished the lower diploma (L.M.P.) and thus the existence of the school was threatened. After long negotiation the council of the school entered into a co-operative venture with the Christian Medical Association of India, Burma, and Ceylon to establish at Vellore a United Christian Medical College for men and women of the M.B., B.S. grade. The first step in this direction was taken when the University of Madras recognized the Vellore Medical School as a college teaching for the pre-registration and pre-clinical subjects in 1942. In 1944 Dr. R. G. Cochrane was asked to become principal in order to assist in the final steps towards recognition for the full M.B., B.S. degree. The Vice-Chancellor of the University visited the college last November, and as a result of his report the Syndicate of the University gave recognition for the clinical subjects. A further University Commission will visit in 1947-8 to report on the progress of the college. It is hoped that by then it will be possible to seek permission from the University for the admission of men students.

Nova et Vetera

"THE POOR MAN'S PHYSICIAN"

There have always been, and there still are, a large number of persons who prefer to indulge in self-medication rather than entrust themselves to the care of the regular medical practitioner. For the guidance of such persons a great mass of literature has been available since the fashion was set by the publication of the *Regimen Sanitatis Salernitanum* of the School of Salerno (Regimen Sanitatis Salernitanum) in mediaeval times. This work was printed in many editions, as also was Andrew Boorde's *Breviary of Health*, which latter is said to be the first original medical work, by a medical man, to be published in England. Such books as these were, no doubt, invaluable in country districts where no skilled aid was available, and this may explain why they were often sponsored by the Laird in Scotland and by the Lord of the Manor in England.

In 1712 there was published in Edinburgh a little book entitled *The Poor Man's Physician, or the Receipts of the Famous John Moncrief of Tippermalloch*. The author was Sir John Moncrief, who owned the estate of Tippermalloch in Perthshire and who was 85 years of age when his book was published. Like so many other works of its kind, it is a mere list of diseases with a large choice of remedies. There is no description of the cause or nature of the malady, such as is found in Boorde's *Breviary*. Some of the methods of treatment have a modern flavour and may be explained in the light of modern science, such as the use of dried blood for haemorrhage and of watercress for scurvy, but for the most part the "receipts" or prescriptions are of empiric nature and the medicaments are often disagreeable or even disgusting. A considerable choice, however, is offered to the patient who may dislike heroic or unpleasant doses.

For example, in "Bleeding of the Nose" the following are a few of the means of treatment suggested:

2. The Blood burnt, powdered, and blown up the nose.
4. Snails in their shells, bruised and put in.
5. Juice of Swine's Dung put in.

21. Sprinkle Hare's Hair on Vinegar and put them up in the nose. This is the best of anything known; it hath not an equal.
22. Blood of a Partridge or Dove wholesomely repelleth bleeding.

For "the Colick," of which no exact definition is given, there are advised:

1. The Hoofs of living creatures are singularly good being drunk.
2. The Heart of a Lark, bound to the Thigh, is excellent against colick.

"Stone in the Kidneys or Dolor Nephriticus" is to be treated by

1. A cataplasm to the Ureters, made of Onions fried with Hog's grease.
2. Whey drunk in summer is best to hinder breeding of the Stone.

A curious nomenclature is occasionally found in this book, the terms used being those employed in certain country districts to this day. For example, "Defluxion of the Windpipe or Wesand"—that is, tracheitis or bronchitis—is to be treated by "A Gargarism of the Juice of Barberries or of Mallow."

Another strange term is still applied to pharyngitis in some parts of Scotland by the patient who announces that "the pap of the halse has fallen down," meaning that his uvula is inflamed and elongated. This diagnosis appears in *The Poor Man's Physician*, where we read: "If the Pap of the Halse be overlax, first dry it with Decoction of Prune leaves or of Comfrey. Then divide an egg in two halves, after it has been well boiled, and apply one half to the Crown of the Head."

The advice of Tippermalloch is full of such nonsense and is of purely empiric quality. It has none of the sound precept to be found in later popular works of the eighteenth century, such as the Rev. John Wesley's *Primitive Physick* and Dr. William Buchan's *Domestic Medicine*, both of which had an enormous circulation.

Correspondence

Mitral Regurgitation

SIR,—It is accepted that mitral insufficiency is associated with stretching of the mitral ring, as, for instance in the failing hypertensive heart. But there is a considerable body of opinion which denies the existence of mitral regurgitation as caused by rheumatic infection. A further stage in this argument is to state that the systolic murmur loudest at the apex and conducted into the axilla is actually a physical sign of mitral stenosis. This assumption is not only contrary to logic but is disproved by cases similar to that here described. That this curious heresy is being taught is clear from the statements of examination candidates.

A young man of 23 was admitted to St Bartholomew's Hospital with fever and joint pains. There was a previous history of rheumatic fever at the age of 19, for which he was kept in bed for two months and was convalescent for a further month. On examination, fever was present up to 102° F., the pulse and respiration rates averaged 110 and 30, respectively. There was clinical evidence of some left ventricular enlargement. A systolic murmur was present, loudest at the apex and conducted into the axilla, blowing in character. No presystolic or diastolic murmurs were audible in any position of the patient. There was no clubbing of the fingers, and no petechiae were seen. The blood culture yielded a pure growth of *Streptococcus viridans* on two separate occasions. He was treated with penicillin 250,000 units daily by intramuscular injection for a month but eventually died. The post mortem examination of the heart showed a pericardium distended with serous fluid, the heart was pale, bulky, and both ventricles were enlarged. The tricuspid and pulmonary valves were normal. The mitral valve was dilated and admitted three fingers. Both cusps showed evidence of chronic thickening. Vegetations were present on the posterior cusp. The whole of the left auricle showed some scarring under the endocardium above the posterior cusp. There would therefore seem to be no doubt that mitral regurgitation due to rheumatism was present, without stenosis, and associated with the classical mitral systolic murmur.

This confirms the opinion of Samuel A. Levine in similar cases. He states in his book *Clinical Heart Disease* (W. B. Saunders Company, 1936, p. 53).

Only occasionally have we an opportunity of examining the valve before stenosis develops—i.e., if subacute bacterial endocarditis becomes superimposed on mitral insufficiency. Then we see that the past history of rheumatism and the moderately loud systolic murmur indicated a true rheumatic mitral endocarditis, producing a regurgitation but no stenosis of the valve, for the pathological examination will show both the old rheumatic and the recent bacterial lesions. The conclusion from the above is that although the diagnosis of organic mitral insufficiency should be made with caution, it is a condition that actually exists, especially in young rheumatic individuals.

The view that mitral regurgitation as such does not occur without mitral stenosis is presumably founded upon post mortem evidence. But this does not take account of the difference in mortality rate according to the presence or absence of mitral stenosis. We do not deny that the common cold or that chicken-pox exists on the grounds that we do not demonstrate them in the post mortem room. There is an identical reason why we should not deny the presence of mitral regurgitation. The legitimate assumption is that this condition is not fatal and it can also be assumed that, in the course of time, stenosis will develop in most cases of regurgitation. But it is inaccurate and illogical to describe the presence of the systolic murmur as evidence of mitral stenosis. By systole is meant ventricular systole, and ventricular systole can only produce a murmur of regurgitation so far as the mitral ring is concerned. Inaccuracy in verbal statement can only engender loose thought. This apical systolic murmur is evidence that mitral insufficiency is at the moment present, which in future is likely to develop into mitral stenosis—I am, etc.,

GEOFFREY BOURNE

Regeneration after Sympathectomy

SIR,—I was surprised to find in the authoritative account by Prof. Paterson Ross (Jan. 5, p. 1) the statement "The sympathetic denervation following a well planned and correctly

executed operation is permanent." Much experimental work on animals has shown that the sympathetic nerve fibres possess uncanny powers of regeneration, being able to find their way through barriers of muscle back to their original distribution (Lee 1929). Simmons and Sheehan (1939) showed conclusively the return of vasoconstrictor activity in the ulnar nerve in many cases of cervico-thoracic sympathetic section, after a post-operative period of several months of complete absence of such activity. They concluded that the return was due to regeneration. Smithwick (1940) has also admitted that regeneration occurs frequently, in spite of "well planned and correctly executed operations."

In a recent study, by modern methods, of the late results of 48 upper limb and 38 lower limb sympathetic sections in Prof. Telford's neurovascular clinic at the Manchester Royal Infirmary, details of which will be published later, regeneration has been found to be the rule rather than the exception, and only 7, all lower, out of the 86 limbs showed no return of sympathetic activity. The extent of the returned activity varied from zero up to complete, but in the great majority of cases was only moderate. On the whole the clinical results in the cases of Raynaud's disease were sufficiently good, as regards the reduction of pain and disability, to make operation well worth while—I am, etc.,

Ocular Signs in the Prisoner of War from the Far East

SIR,—Major G. C. Dansey-Browning and Capt. W. M. Rich (Jan. 5, p. 20) describe ocular signs in a group of prisoners of war returned from the Far East. This condition has been seen by many of us during the past six months and I am entirely in agreement with their observations, but not with their conclusions. I have now seen this ocular condition in prisoners returned from Rangoon, Singapore, Hong Kong and Java including both Indian and British and some of the cases I have seen are probably included in their paper.

These prisoners show an interesting syndrome of which the ocular signs appear to be a constant feature but there is commonly bilateral nerve deafness, of varying degree with a spinal cord syndrome. The latter is usually a picture of posterior column dysfunction (but occasionally with pyramidal signs), the legs being affected more than the arms. In at least two cases the syndrome has been further complicated by intellectual deterioration. This curious condition was discussed in some detail by Dr. Spillane and myself at the meeting of the Neurological Section of the Royal Society of Medicine held in November, 1945 and has been fully described by Spillane and Scott (*Lancet*, 1945, 2, 261).

That this syndrome is due to a dietary deficiency seems almost certain, but it seems equally certain that it has nothing whatever to do with vitamin B₁. It is very doubtful whether it has anything to do with B₂ and certainly, in some of my cases, the syndrome has existed throughout its course with no evidence of beriberi or pellagra. At the same time, scrutiny of the diet on which this picture develops suggests that the deficiency is probably in the B group of vitamins, though a deficiency of vitamin A has not yet been excluded. It seems probable that in the past the ocular signs have frequently been noted in people suffering from dietary deficiency, and, because they have also had the classic signs of beriberi or pellagra the failing vision has been ascribed to the same common factor but in most of these cases the diet is deficient in practically all vitamins.

I have little doubt that, as Dansey-Browning and Rich say, some of their cases did in fact suffer from beriberi but I would suggest that the beriberi was a coexisting deficiency picture. They are probably quite correct in thinking that the failure of vision is an irreversible process and this has now become an important problem as the number of affected ex-prisoners in this country is probably running into hundreds, if not thousands. Although agreeing that the lesion underlying the visual failure lies in the optic nerve, I do not like the term "retrobulbar neuritis," as there is less than no proof that this is an inflammatory condition—I am, etc.,

Investigations of Remedies

SIR.—The penultimate paragraph in Dr. G. H. du Boulay's analysis of 39 cases treated with penicillin cream of low concentration (Jan. 12, p. 50) prompts me to draw attention to the uselessness of analyses the basis of which is the application of a multiple compound to a pathological condition, and the inference, if the condition improves, that the improvement is due to any one particular content of the multiple compound. No mention is made in this analysis of controls—i.e., identical treatment in all respects, ointment, washing, etc., of similar conditions, with the deletion of the remedy whose action is being studied. This method of investigation constitutes a general principle which is much too frequently omitted in reports of investigations purporting to evaluate remedies, and unless it is adopted the general "lack of faith" will, quite rightly, continue.—I am, etc.,

Leeds

C. G. KAY SHARP.

Lymphangitis Mesenterialis

SIR.—Reading Mr. Ian Aird's article on this subject (Nov. 17, 1945) I could not help feeling disappointed or rather sad. I quote: "Non-specific mesenteric lymphadenitis has found no general acceptance, etc." Alas! this seems to be true. Since about twenty years ago, when, on the basis of a clinical and surgical experience of many years, I first described in detail the clinico-pathological features of non-specific acute and chronic lymphangitis mesenterialis as a new, hitherto practically unknown,* but nevertheless very characteristic disease, I have tried in my articles written in many languages, in my lectures to students and postgraduates, in my papers at international professional meetings, etc., to convince the medical profession of the practical importance of this disease. I particularly emphasized the fact that a safe diagnosis can be clinically established, especially in chronic cases. Moreover, up to the present time I thought that I had been successful in my efforts. Medical practitioners in Central Europe, in France, in this country, in India, and even in China, where I have recently been working, were able clinically to establish the correct diagnosis and to admit cases for operation. But, as Mr. Aird rightly says, nothing can be found in the textbooks. In the past few years I have not published any more papers on this subject, because I was actually afraid of becoming a bore with my lymphangitis mesenterialis. Some members of the medical profession even did me the honour of naming it "Pribram's disease." But this of course is of little importance (hypocrisy compels me to say).

However, the first feeling of disappointment quickly yielded to full appreciation when I continued to read the description and detailed statement contained in Mr. Aird's paper, with which I fully agree. But I take the opportunity of adding a few points from my personal experience which might be of interest to the reader. I have frequently been asked why I call the disease lymphangitis mesenterialis. The answer is that the whole lymphatic system of the abdominal region is often generally affected, including, for instance, the complicated lymphatic system of the liver. Lymphadenitis mesenterialis is only one easily recognized part of the whole pathological feature. I have devoted years of special study to this liver lymphangitis, which I named lymphangitis hepatica. All relevant details will be given in my book on the hepato-biliary diseases, which I hope will soon appear in print.

I have always emphasized the point that the classical mesenteric or abdominal lymphangitis is not due to a local intestinal infection and direct propagation. It represents a general infection, with the tonsils as the most frequent way of entry. Its localization in the ileo-caecal region is intimately associated with what I have called the "lymphangitic form of appendicitis." In this form the infection does not start in the mucosa, but spreads throughout the subserous lymphatic spaces. This form frequently shows an epidemic-like appearance—a puzzling fact unless one realizes that it is a blood-borne infection, in most cases following upon tonsillitis. The connexion with tonsillitis is also an outstanding feature in lymphangitis mes-

enterialis, in both its acute and chronic forms. The tendency to recurrent attacks after a flaring up of chronic tonsillitis constitutes a great diagnostic help when inquiring into the patient's history.

The "navel colic" of children (a term used by the old authors) is nothing other than lymphangitis mesenterialis, the pain around the navel being caused by acute swelling of the mesenteric glands. But this affection is not confined to children, for I have observed it in persons up to 25 years of age. I fully agree with Mr. Aird that it predominates in the male sex. It is rarely observed in females—a fact which has some pathological reasons and significance.

The acute form is characterized by a considerably high rate of mortality. Patients are usually operated on for acute appendicitis. They are apt to die on the third or fourth day with symptoms of "abdominal sepsis," a term sometimes applied in old textbooks to such cases. The term is quite correct. The condition is actually an abdominal sepsis and not peritonitis in the usual sense, as is observed after rupture of an abdominal viscus.

In a great many cases microscopical and bacteriological examination of the inflamed glands was carried out by myself and my assistants. The microscopical findings show oedema, hyperplasia to the extent of the so-called "sinus catarrh." Suppuration is rare. Bacteriological examination revealed streptococci in a few instances and more rarely staphylococci. But the percentage of positive findings was so low that I doubt whether a purely bacteriological point of view can give a satisfactory explanation of the pathology of the disease. I have good reason to believe that in a hypersensitive lymphatic system in young male subjects allergic conditions also play a part. Although I must leave the details of this matter for another communication, I may here point out that Fisher, my co-workers, and I myself have succeeded in producing similar pathological conditions in guinea-pigs sensitized with pig serum.

The chronic form is characterized by the tendency to recurrent attacks. When questioned the patients very often reveal the important fact that the abdominal pain followed a flaring up of a chronic tonsillitis. In some cases a very severe cold or an attack of influenza culminated in so-called "abdominal influenza." In other words, these recurrent attacks of pain are definitely connected with an infection of the upper respiratory tract, in both time and aetiology.

With regard to treatment, as the diagnosis in acute cases can rarely be made with certainty except when the appendix has already been removed, laparotomy is the safest procedure. Indications are always given in the acute cases which appear under the alarming symptoms of an acute abdomen. In recurrent attacks of chronic forms three measures have to be considered and have proved satisfactory: (1) tonsillectomy, (2) protein therapy, (3) x-ray treatment.—I am, etc.,

London, S.W.1.

B. O. C. PRIBRAM.

Spinal Analgesia

SIR.—I cannot allow Dr. N. Beattie's comments (Jan. 5, p. 31) to pass unanswered. He points out that I do not mention spinal analgesia in discussing the anaesthetics used in my series of appendicitis cases. The reason for this is that I only very rarely use spinal analgesia for appendectomy, and then only when there are definite indications, such as respiratory trouble. In the ordinary case of acute suppurative appendicitis I feel that it is quite unnecessary to use an anaesthetic which lasts for over an hour when the operation can be done in 15 or 20 minutes. In the very ill cases which I mentioned in my article I am certain that a spinal analgesic would have prejudiced the patients' chance of recovery. In these cases I found that a very quick laparotomy under nitrous oxide and ether was by far the least "shocking" method.

I cannot agree with him that I have been working at a disadvantage because 80% of my anaesthetics were given by house-surgeons. Since the beginning of 1944 I have had no professional anaesthetist at my hospital and nearly all my anaesthetics have been given by my house-surgeons or resident surgical officer, only the spinal analgesics and certain of the local infiltrations being done by myself. From the beginning of 1944 until the middle of 1945—that is to say, the time during which I did a large part of the series of cases published—a

* In 1920 Wilensky (*Med. Rec.*) reported shortly three cases, one of which has, however, proved to be of a tuberculous nature. Anyway this author emphasizes the existence of a non-specific acute mesenteric lymphadenitis.

total of 3,518 anaesthetics were given at the hospital. Of these, 39 were chloroform, 401 gas and oxygen, 601 gas, oxygen, and ether, and 1,951 open ether. There were 108 spinals and 418 local infiltrations or regional blocks. Dr Beattie must not consider that we have not been discriminative about our anaesthetics because they were given by house surgeons. Each case is studied before operation in order that the proper anaesthetic may be chosen. It is my belief (if I may open an old controversy) that the surgeon rather than the anaesthetist is the person who should decide which anaesthetic should be given, and, personally, I have found it much easier to deal with house surgeons than with the professional anaesthetist. Dr Beattie will also note from the above figures that I have no animosity against spinal analgesia, although I do not use it in appendicitis cases. Unlike him I generally use heavy puerperine, and have had no complaints of post-operative headache. Using this drug, it is possible by suitable posture to make the analgesia very selective so that a low or unilateral block may be got, thus avoiding a dangerous fall of blood pressure in a very elderly individual. I invariably use spinal analgesia for resection of the colon or rectum, and for Smith Petersen operations.

I feel that the professional anaesthetist does not make sufficient use of local analgesia. There are few emergency operations which cannot be carried out by this means, and I have found it particularly useful in abdominal surgery, where complete abdominal analgesia and relaxation can be obtained by the paravertebral intercostal block, with or without splanchnic infiltration. I have found that partial gastrectomy in particular can be readily done in this way with the minimal amount of shock. I have also found it extremely valuable when doing a Smith Petersen operation in an elderly individual, a patient aged 88 being recently done in this way and making an uninterrupted recovery.

Finally, I may point out that I have found my lack of a professional anaesthetist to be a relatively small disadvantage and the best tribute I can pay to the quality of my house surgeons is to state that during the eighteen-months period in question there was not one anaesthetic collapse in the 3,518 anaesthetics given—I am, etc.,

Greenock

A LYALL

SIR.—In reply to the letters of Drs Helen B Alcock and H W Loftus Dale (Dec 8, 1945, pp 818, 819) I should like briefly to make the following points:

1 *Risks*—I am of the opinion that these have been grossly exaggerated. Of course, there is a risk in using any anaesthetic, particularly in the wrong patient. In my experience, however, such risks did not manifest themselves as often as one is made to believe. Dr Dale may be interested to know that I started to use heavy nupercaine in obstetrics only 3½ years ago, with the mere theoretical knowledge of this "dangerous form of anaesthesia." I would certainly have commenced its use earlier had I not been deterred by the adverse criticisms in the literature levelled at spinal analgesia in obstetrics as a whole. That an alarming drop in blood pressure in cases of abdominal distension often occurs is contrary to my experience. Theoretically one should expect such an occurrence, but practically it is rarely met with. During the past 3½ years we have employed spinal analgesia, using heavy nupercaine, in 660 obstetrical cases (190 Caesarean sections and 470 vaginal deliveries) and in 840 gynaecological operations. During this time only six cases of so-called "alarming drop in blood pressure" have occurred, without a single fatality directly due to the spinal analgesia. Surely Dr Alcock will not wish to abandon all forms of analgesia in obstetrics because of the possible risks entailed? I would be very interested to know how many such alarming experiences were encountered in the personal experience of the above named, using heavy nupercaine.

2 *Premedication*—The detrimental effects of premedication on newborn infants have surely been exaggerated. The harsh armchair criticisms that omopon gr 1/3 (22 mg), scopolamine gr 1/300 (0.2 mg) may produce severe foetal apnoea, and even stillbirths, are surely unfounded. I have never seen such an occurrence following Caesarean section. Almost every infant has cried lustily immediately on extraction. As house surgeon at St Mary's Hospital, Manchester, I had ample opportunity to witness many cases of Caesarean section performed under local anaesthesia, with premedication of morphine gr 1/4 (16 mg) and hyoscine gr 1/150 (0.4 mg). I am sure the members of the staff at St Mary's will bear me out when I say that no case of foetal apnoea occurred, let alone stillbirths. In operative vaginal delivery, however, the ill effects of sedation on the infant are well known and, of course, I deprecate its use. Dr Alcock misquoted me in suggesting that I employed premedication of omopon and scopolamine for vaginal deliveries. On the other hand, is not

foetal apnoea frequently encountered after "minimal ether or trilethal or under cyclopropane O," particularly in cases of foetal distress? Indeed, I would go so far as to say that even a minimal of general anaesthetic is sufficient to "put the finishing touches" to an infant in severe distress.

3 *Inhibiting Action*—The inhibiting action of spinal analgesia on the longitudinal muscle fibres, while increasing that of the circular fibres of the uterus, would theoretically contraindicate the use of such analgesia for vaginal delivery. I think I can reassure Dr Dale that in practice few difficulties are encountered in intrapartum manipulations, complications in the third stage being rare. A striking feature of spinal analgesia is the absence of shock following destructive and difficult forceps operations.

4 *Suitability of the Method*—That the majority of patients prefer to be asleep during the operation is again contrary to my experience. Not only have the women been unaware of delivery under a spinal analgesia, but have been delighted to hear the cry of the child immediately on extraction. Women who have had repeated operations have asked for spinal analgesia a second or even a third time.

5 *Headache*—I will agree that this was a serious complication early on in many series of cases. Improvements in technique and after-care have, however, led to such a striking diminution in its incidence that only two cases of severe headache have occurred in the last 266 cases. Surely a spinal headache is not too big a price to pay for the striking absence of the "burst abdomen," bad chest signs in the presence of painful abdominal wounds, and the like.

Finally I would like to reiterate my earlier conclusion, that spinal analgesia using heavy nupercaine is safe and reliable in operative obstetrics in selected cases of advanced pregnancy and would make a plea for a further extended trial of this form of analgesia—I am, etc.,

Salford

LOUIS RESNICK

SIR.—Dr N Beattie's excellent letter raises some points of interest to surgeons and anaesthetists. There is no doubt that spinal analgesia minimizes the difficulties of the surgeon working inside the abdomen and—as he says—the amount of bleeding is very much less than when ether is used. If he implies, however, that the use of spinal analgesia in preference to ether lessens the incidence of chest complications he is treating on more controversial ground. The published figures do not lend much support to this idea.

Many anaesthetists, myself among them, will nevertheless agree with him that spinal analgesia is the method of choice for most lower laparotomies, especially when the surgeon cannot call upon an anaesthetist skilled in other methods. But it should be the aim of anaesthetists as a body to see that surgeons are not placed in such a position (except, of course, in special cases like that of the ship surgeon of which Mr Beattie makes timely mention) and for a surgeon to give the spinal analgesic himself when a skilled anaesthetist is present as Mr Beattie advocates, strikes me as uneconomical, to say the least. An anaesthetist who is relegated to the position of "moral minder" to a patient anaesthetized by someone else will set himself to the task with less conviction than if he had given the spinal himself, and if more active measures should be needed the advantage of having the anaesthetist responsible for the whole conduct of the anaesthetic becomes doubly obvious—I am, etc.

RONALD WOOLMER.

SIR.—I cannot agree with Dr N Beattie in his letter (Jan 3, p 31) when he states that "no doctor should go as a ship surgeon without being master of one technique for the administration of spinal analgesia," for the very reason that conditions at sea, for the most part, contraindicate its use. Dr Beattie himself asserted that "utmost attention to detail is necessary for success with spinal analgesia" and with this I entirely agree, but he goes on to stress the importance of "keeping the head low for 24 to 48 hours—the longer the better—to avoid headache." Lone young doctors (and some not so young, for that matter) however, mostly find themselves in small ships and there is a substantial difference between conditions ashore and afloat in small ships. Owing to pitch and roll it would be only on rare occasions that he could be reasonably sure that a patient's head would remain in the low position and then it is always uncertain how long such ideal conditions will prevail.

One therefore cannot help challenging the statement that it is "safer for the patient," for this is certainly not the case.

ing specially attractive equipment, quarters, and facilities—a procedure which would have the advantage of enticing the better doctor into the area. A combination of these two measures would probably be more effective than either alone.—I am, etc.,

B.A.O.R.

R. W. CROCKET,
Squad. Ldr.

Questionnaires, Past and Future

SIR,—Dr. Robert Ritchie makes a very timely suggestion that an up-to-date questionnaire should be drawn up forthwith and sponsored by the B.M.A. The seven questions he offers for consideration are straightforward and unequivocal. If the B.M.A. really claims to reflect the recent views of its members can it offer any cogent reason why this questionnaire should not immediately be issued, or can it suggest how better such recent views could be ascertained?

There is little doubt about the meaning of the apparently generous offer of the State to buy up practices; it is nothing other than a political manoeuvre to gain control of medical men who hitherto have been a little difficult to regiment, but who, with their livelihoods at stake, may the more readily be persuaded to "eat from the hand" if they be but fools enough to accept at its face value this transparent act of generosity and sell their souls for a "mess of pottage." Who is Mr. Aneurin Bevan that he should decree that "it is highly improbable that I will permit the sale and purchase of practices"? Hitler issued just such edicts. We do not look with equanimity on similar pronouncements in this country. Are we freemen or bondsmen and are we to sit idly by while, by the stroke of a pen or the issuing of a regulation, our liberty and freedom of livelihood are filched from us?

Cannot our Association be strong enough to give us a lead when leadership is obviously needed? Armed with the mandate from a fresh questionnaire our negotiators would then be in touch with "up-to-the-minute" professional feeling. Until housing, feeding, clothing, and education are adequate State medicine at this juncture can be but a parrot cry to trap the unwary in so far as it offers improved health to the community; but State control of the doctor is a powerful political weapon for controlling all units of the population through a medical civil service owning allegiance only to a soulless State, from whom alone then would come its daily bread.—I am, etc.,

St Annes, Lancs

G. H. URQUHART.

Obituary

J. FALCONER HALL, C.M.G., M.B., C.M.
Surg. Rear-Admiral, R.N. (ret.)

We regret to announce the death of Surg. Rear-Admiral J. Falconer Hall at Chudleigh, Devon, on Jan. 15. After his retirement from the Navy, at the end of a distinguished career afloat and ashore, he was appointed in 1931 a Commissioner of the Board of Control for England and Wales, and held that post until 1938.

John Falconer Hall, son of William Hall, was born on Feb. 23, 1872, and studied medicine at the University of Aberdeen, graduating M.B., C.M. in 1893 and entering the R.N. Medical Service in 1895. After active service on the China Station, for which he was mentioned in dispatches, specially noted to staff surgeon, and awarded a medal, he won the Gilbert Blane gold medal in 1902 under a deed of trust held by the Royal College of Surgeons of England from Sir Gilbert Blane, F.R.S., the Naval sanitary reformer. In the war of 1914-18 he served in the battleship *Hannibal* at Scapa, in the battle-cruiser *Australia* with the Grand Fleet, and as senior medical officer of the hospital ship *Soudan*. For these services he was again mentioned in dispatches and created C.M.G. In 1919-20 he was Deputy Director of the Medical Department of the Admiralty, and in 1920-3 second in charge at Haslar Hospital at Malta. He held the appointment of Honorary Surgeon to the King from January, 1925, until September, 1938.

Admiral Falconer Hall had joined the B.M.A. in 1899 and sat on the Council as representative of the R.N. Medical Ser-

vice from 1928 to 1932; he was also a member of the Navy and Military Committee and the R.N. Subcommittee and the Committee on Medical Branches of the Fighting Service which reported fifteen years ago. In 1942-3 he held office president of the United Services Section of the Royal Society of Medicine.

H. A. B. WHITELOCKE, T.D., M.Ch., F.R.C.S.

Hugh Whitelocke, who died in the Acland Home on Jan. 12, will be sincerely mourned by a host of friends in Oxford and elsewhere.

He was born in Oxford in 1891, the eldest son of Mr. H. R. Whitelocke, himself a well-known surgeon and a member of the honorary staff of the Radcliffe Infirmary. He was educated at Summerfields, Rugby School, and Christ Church, and completed his medical training at King's College Hospital in 1914. After qualification he saw service in the Sudan and elsewhere during the 1914-18 war, after which he returned to Oxford and specialized in surgery. He became a Fellow of the Royal College of Surgeons of Edinburgh in 1924 and of England in 1925, and in 1926 he became a Master of Surgery of Oxford University, one of the highest surgical qualifications. He was Fellow of the Association of Surgeons of Great Britain and Ireland, ex-president of the Oxford Medical Society, and the author of numerous articles on surgery. He was elected an honorary assistant surgeon to the Radcliffe Infirmary in 1919, and became a full honorary surgeon in 1926. Thenceforward, until the second world war broke out, he practised as a consulting surgeon in Oxford, and in course of time became the senior surgeon at the Radcliffe Infirmary as his father had done. In 1939 he was appointed to command a Territorial General Hospital (the 16th British General Hospital) with the rank of colonel. He mobilized this unit, which consisted largely of local men, the Examination Schools and took it to France in January 1940. When France was invaded the hospital was evacuated from Boulogne just in time to avoid capture. Soon afterwards Whitelocke was invalided out of the Army and resumed his work at the Radcliffe Infirmary, and in the neighbourhood of Oxford at a time when an acute shortage of surgeons placed a great strain upon him and his colleagues. Although his health was not good, he continued to play an active part in the surgical work of the Infirmary, which had become a medical school in 1939. In addition to his appointment in the Radcliffe Infirmary he was the honorary consulting surgeon to Moreton-in-the-Marsh, Buckingham, Shipston-on-Stour, a Thame Cottage Hospitals, and to the National Hospital for Diseases of the Heart at Maids Morton. He also held the post of Litchfield Lecturer in Surgery and clinical examiner in surgery in the University of Oxford. He had been honorary secretary of the Oxford Division of the B.M.A. and vice-president of the Section of Surgery at the 1936 Annual Meeting.

Hugh Whitelocke was one of the most sociable and hospitable of men, and never allowed his exacting professional work cut him off from social intercourse with his large circle of friends. He was a very effective, if somewhat unorthodox golfer, and was a regular player at Frilford, of which club was captain in 1936. He was a member and Past Master of the Churchill Lodge of Freemasons and a member of Apollo Lodge. He was also a keen bridge player and a good shot. While an undergraduate he was a member of the Church Rugby XV, and subsequently became surgeon to the University team.

The qualities which those who knew him will remember were his invariable courtesy, good temper, and geniality, and the fact that he rarely, if ever, said or did an ill-natured thing. His wide professional practice, his good manners, and his friendly disposition made him one of the most popular and best known men in the neighbourhood of Oxford, and he will be greatly missed by a quite exceptionally large number of patients and personal friends. In 1934 he married Miss Madeleine Shankland, who joined with him in all his social activities and shared his popularity.

E. C. B.

Mr. HERBERT JAMES MARRIAGE, consulting aural surgeon St. Thomas's Hospital, died at the age of 73 at Woldingham, Surrey, on Jan. 12. He had been secretary of the Section of Otology at the Annual Meeting of the British Medical Assoc-

union in London in 1910 and president of the Otolological Section of the Royal Society of Medicine in 1915. Educated at the City of London School and St Thomas's Hospital, he took the Conjoint diploma in 1897, the M.B. Lond. in 1899, and the B.S. two years later, and was admitted F.R.C.S. in 1902. His early posts at St. Thomas's were those of house-surgeon, house-physician, surgical registrar, and surgical tutor. After studying otology and rhinology at clinics in Germany, he was elected aural surgeon to St. Thomas's in 1904, and held that post until his retirement in 1932. He was also aural surgeon to the London Fever Hospital for three years, and clinical teacher in otology and rhinology at the Royal Army Medical College. Marriage published a number of papers on his speciality in the *Lancet*, the *Transactions of the Otolological Society* and the *Journal of Laryngology, Rhinology and Otolology*.

Mr JOHN WILLIAM HEEKES, M.B., B.S. Lond., who died at his home in Barnes in November last, will leave a position very difficult to fill by any one person, for he persistently did the work of two, especially at Richmond Royal Hospital, where he had been honorary surgeon for 25 years. His consuming passion and major hobby was surgery, and for this work his energy was apparently unlimited, and still undimmed after long nights of operating on war casualties in the dark days. Besides being a general surgeon he was also the gynaecologist at Richmond and lecturer to and examiner of nurses, and in addition had a large private practice, in later years almost entirely surgical. His wide taste and practice in surgery was foreshadowed early in his training, for, besides being house surgeon after qualifying in 1906, he was later resident obstetric officer and clinical assistant to the throat and ear department at Charing Cross Hospital, keeping in touch with hospital teaching long after starting to practise. He became captain, R.A.M.C., in the 1914-18 war and was attached to 46 C.C.S., later becoming surgeon to St. Andrew's Hospital at Malta and to Queen Alexandra's Hospital at Millbank. After the war he was surgeon specialist to Belmont Hospital, where up to 1,400 German prisoners passed through his hands, and this unusual and concentrated surgical experience decided him to forgo general for surgical practice. In 1920 he was elected honorary surgeon and later gynaecologist to Richmond Royal Hospital—positions which he filled admirably and energetically. During this last war he was surgeon specialist, E.M.S., at Richmond and was later in charge of the fracture clinic. In 1929 he was appointed lecturer and examiner in surgery and gynaecology by the General Nursing Council—a position which he enjoyed and in which he was deservedly popular. He was direct in manner, very outspoken when necessary, but a most amiable colleague to work with, and possessed of a smile of real charm most reassuring to patients. As a surgeon he was courageous and bold to a startling degree once he had decided on the correct course of action, he was rapid and untiring and had that sound sense of judgment that only comes from long experience and intelligent consideration of his subject. As he worked, so he relaxed—energetically. He was a good horseman and used to ride regularly, he took long holidays abroad whenever possible and had been to and appreciated most of the European countries. A few years ago he bought a farm and with his accustomed energy threw himself into the problems confronting smallholders, but the outbreak of war largely hindered his activities in this direction. His last illness, which was a protracted one of over a year, he bore with unusual fortitude and cheerfulness maintained up to the end.—C.H.C.

We regret to announce that Dr HAROLD JOHN VAN PRAAGH of Hampstead, died on Jan 15 after a long illness. He was born in London in 1877 son of William Van Praagh and studied medicine at St. Mary's Hospital, where he won a natural science scholarship and the Meadows scholarship in midwifery and gynaecology. Having graduated M.B. Lond. with honours in medicine in 1899, he held a series of house appointments at St. Mary's, and was for a time casualty physician. He took his M.D. degree in 1901. During part of the last war he served at the Cambridge Hospital, Aldershot, with the temporary rank of captain, R.A.M.C. Dr Van Praagh, after settling in practice in Langland Gardens, N.W., became honorary anaesthetist to the Hampstead General Hospital and to the Hospital of St. John and St. Elizabeth. He was a member of the Council of the Hampstead Medical Society, and chairman of the Hampstead Division of the B.M.A. in 1925-6.

Dr JAMES KENNETH WATSON died on Dec 9, 1945, from injuries received when he was knocked down by a motor car in Bournemouth. Dr. Watson was born in 1870 and received his medical education at the University of Edinburgh, where he graduated M.B., C.M. in 1892, proceeding M.D. four years

later. After qualifying he held successively house posts at Morpeth Dispensary, Sheffield Royal Hospital, Sheffield General Infirmary, and Essex and Colchester Hospital. In 1896 he settled in practice at Byfleet, Surrey, where he became medical officer and public vaccinator to the Chertsey Union, and medical officer to the Post Office. He moved to Sidenham in 1910, and in 1914 became M.O.H. for Stevenage and assistant medical inspector of schools for Hertfordshire. He served as a captain in the R.A.M.C. in the war of 1914-18. He was for a time a member of the Lord Chancellor's Pension Appeal Board. Dr. Watson was the author of *Handbook for Nurses* which passed through eleven editions, *Handbook for Senior Nurses and Midwives* and *Anaesthesia and Analgesia for Nurses and Midwives*. He had been a member of the B.M.A. for many years.

Dr DONALD GEORGE SUTHERLAND, who died at Ealing on Jan 10 in his 83rd year, had been chief bacteriologist to the Metropolitan Water Board laboratories and was well known as an authority on water analysis. He was educated at Watson's College and the University of Edinburgh, graduating M.B., C.M. in 1886 with the University medal in medical jurisprudence and public health, and taking the B.Sc. in Public Health three years later. In 1890 Dr Sutherland became M.O.H. for the County of Sutherland and Burgh of Dornoch, some years later he was called to the Bar by the Middle Temple, and in 1900 entered as an advanced research student at St. John's College, Cambridge, receiving the M.A. degree of that university. After a period as assistant bacteriologist in the Local Government Board laboratories he was appointed bacteriologist to the M.W.B. in 1905. He wrote a succession of nine sanitary reports on the County of Sutherland and a dissertation on certain spore-bearing anaerobic organisms considered as criteria in the bacteriological examination of water supplies. He had been a member of the B.M.A. for 38 years.

The Services

Major Gen. Oburne Ievers, C.B., D.S.O., M.B., late R.A.M.C., has been appointed Colonel Commandant of the R.A.M.C., and Major Gen. John Percival Helliwell, M.R.C.S., L.R.C.P., L.D.S., Colonel Commandant of the Army Dental Corps, for 1946.

The following have been mentioned in despatches in recognition of gallant and distinguished services in Italy: Col (Temp) W. A. D. Drummond, O.B.E., R.A.M.C. Col G. R. Forbes, E.D., Lieut. Col. W. K. Bice, L. E. R. Luckey, and H. S. Mitchell, Major's D. K. Grant and J. S. Maclean. Capt's W. M. Biers and J. G. W. Swanson, R.A.M.C.

The following appointments and awards have been announced in recognition of gallant and distinguished services in Burma:

C.B.E. (Military Division)—Brig (Temp) H. G. Winter, M.C., V.S. late R.A.M.C. Brig (Acting) G. B. Jackson, I.M.S.

O.B.E. (Military Division)—Lieut-Col (Acting) K. J. Dunlop, Lieut. Col. (Temp) H. V. Ingram, R. T. Johnson, D. M. Baker, A. Burns, M.C., J. McI. D. McIntosh, and W. H. Wolstenholme, M.B.E., R.A.M.C. Lieut-Col (Temp) A. E. Kingsford, I.M.S.

M.B.E. (Military Division)—Lieut-Col (Temp) J. F. Heslop, Majors (Temp) J. V. Crawford, W. Drummond, F. Evans, M.C., H. G. Page and J. P. Scrivenner, Capt's G. A. Craze, C. M. MacGeach, A. McDiarmid, E. Rentoul, and C. E. S. Myers, R.A.M.C. Lieut-Col (Temp) G. V. Chaphekar, Major (Temp) M. P. Ali, and Capt's A. D. A. Maconochie and J. L. G. Pinto, I.M.S. Lieut's C. R. Narayan and H. Ali, I.A.M.C.

D.S.O.—Lieut. Col. (Temp) J. R. Kerr, I.M.S.
M.C.—Major (Temp) W. J. Ramsay, and Capt's E. G. W. Clarke and L. Wilson, R.A.M.C. Capt's T. L. W. McCullagh and V. Chittor, I.M.S. Capt (Temp) D. Ramanath, and Lieut. Gangaprasad, I.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Killed in air crash on way home from India—Capt. Paul Verner Isaac, R.A.M.C.

The estimated expenditure of the Bradford and County Joint Cancer Committee for 1946-7 in respect of the Radium Institute is £21,305, including £12,445 for salaries. The end of the war has enabled the Committee to secure a more normal staff, especially on the technical side, and to increase its estimate of costs. The chief contributors are the Bradford Corporation, £7,180; Royal Infirmary, £5,340; and the West Riding County Council, £7,775.

Universities and Colleges

Medical News

UNIVERSITY OF CAMBRIDGE

The subject of the present course of lectures on the History of Science, in the Mill Lane Lecture Rooms on Saturdays at 12-noon, is the development of experimental science with special reference to the nineteenth century. On Feb. 23 Prof. H. Hartridge will lecture on discoveries in animal physiology; on March 2 Sir Henry Dale, on experiment in medicine; and on March 9 Prof. F. C. Bartlett, on experimental psychology.

During December, 1945, the title of the degrees of M.B., B.Chir. was conferred on C. E. Cooper, of Girton College.

UNIVERSITY OF GLASGOW

At a ceremony of graduation, held on Jan. 12, the following medical degrees were conferred:

M.D.—A. K. MacRae (with honours), Constance A. C. Ross (with commendation), W. McAdam.

M.B., Ch.B.—J. Rankin (with commendation), J. M. Adam, J. K. Anderson, J. Austin, Elizabeth Boothe, J. Buchanan, R. W. Campbell, G. A. Carnahan, D. B. Carruthers, D. Clark, D. S. Cranston, J. S. Creighton, Isabella G. MacL. Cunningham, J. M. Harper, R. R. Houston, K. Jack, W. A. Jackson, M. Laidlaw, R. M. Lang, J. W. Little, J. A. McCusker, N. McDougall, J. A. W. Maguire, D. H. Munro, J. D. Nelson, T. C. Nicol, J. H. Noble, J. M. O'Brien, R. H. Park, J. D. Paterson, J. Prentice, I. F. F. Rae, J. H. R. Ramsay, W. Ramsay, R. C. Robb, Jean W. Roberts, W. Roy, Betsy D. Scott, W. L. Selkirk, D. C. V. Stewart, Elizabeth Stewart, T. Thomson, W. F. Toomey, J. L. F. Wyllie.

The Bellahouston Medal for eminent merit in thesis for the degree of M.D.: T. Anderson.

UNIVERSITY OF ST. ANDREWS

The following candidates have been approved at the examinations indicated:

M.B., Ch.B.—D. A. Kerfoot (with commendation), W. K. Bryson, J. H. Burt A. Douglas, I. C. Geddes, Katherine M. Kelly, H. A. F. Mackay, Joan C. Main W. B. Wallace, Margaret A. M. Wilson.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The Moynihan Lecture was delivered on Jan. 9 by Prof. Willem Noordenbos, professor of surgery in the University of Amsterdam. Immediately before the lecture Prof. Noordenbos was admitted to the Honorary Fellowship of the College to which he had been elected in 1943 while in captivity under the Germans. On Jan. 10 Sir Henry Dale, formerly President of the Royal Society, and Sir William H. Collins, the greatest living benefactor of the College, were also admitted Honorary Fellows.

The First Lord of the Admiralty presented the Gilbert Blane Medal to Surg. Lieut.-Cmdr. F. P. Ellis, R.N., awarded to him for his observations on the effect of the thermal environment on the health and efficiency of ships' companies working in the Tropics under active-service conditions and at action stations. The Medical Director-General of the Navy and the President of the Royal College of Physicians of London witnessed the presentation.

At a meeting of the Council on the same day, with Sir Alfred Webb-Johnson, President, in the chair, Prof. F. Wood Jones was admitted as the first Sir William H. Collins Professor of Human and Comparative Anatomy.

It was reported that Sir James Walton would deliver the Hunterian Orator for 1947 and Sir Heneage Ogilvie the Bradshaw Lecture for 1946.

The Council received with gratification gifts to the restoration and development fund of \$5,000 from the staff of the Mayo Clinic and the Faculty of the Mayo Foundation and of £N.Z.500 from the New Zealand Division of the Royal Australasian College of Surgeons on behalf of the Fellows of the English College in New Zealand.

It was reported that the remainder of the library books and the College collection of portraits and busts had been brought back to London from their various places of safety in the country.

It was agreed to institute a club in the College for Fellows, Members, and Licentiates in Dental Surgery and the members of all the associations linked with the College through the joint ceteriat at No. 45, Lincoln's Inn Fields.

It was decided to hold a meeting of Fellows on Wednesday, May 8, at 6 p.m.

Diplomas in Psychological Medicine and in Laryngology and Otology were granted jointly with the Royal College of Physicians of London to the following successful candidates:

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—A. Conachy, A. J. F. Crossley, J. E. Duffield, P. E. Sundt, T. G. Williams.

DIPLOMA IN LARYNGOLOGY AND OTOTOLOGY.—F. Badrock, R. V. Blaubaum, L. Boss, T. McM. Boyle, L. C. Jacobson, H. Jelinek, A. E. Khan, H. E. McHugh, W. J. O. Page, W. M. Ritchie.

Correction.—An asterisk should have appeared against the name of K. D. Roberts in the University of Birmingham pass list published in this column on Jan. 12 (p. 72), thus indicating that he had graduated M.B., Ch.B., with second-class honours.

The Scientific Committee and Trustees of the R. L. St. J. Harmsworth Memorial Fund have awarded £5,000 to Sir Alexander Fleming and £2,500 each to Sir Howard Florey and Dr. E. Chain in recognition of their work with penicillin in the treatment of infective endocarditis. The presentation was made by Lord Horder on Jan. 22.

At a meeting of the Medical Society for the Study of Venereal Diseases, 11, Chandos Street, Cavendish Square, W., to-day (Saturday, Jan. 26), at 2.30, Dr. Drapkin will convey greetings from the Chilean V.D. Society, and Major M. H. Salaman, R.A.M.C., will give an address on "Non-specific Genital Infections," followed by discussion.

The next meeting of the Middlesex County Medical Society will be held at Kodak Works, Wealdstone, Harrow, on Thursday, Jan. 31, at 2.30 p.m.

The Association for Scientific Photography (Tavistock House North, Tavistock Square, W.C.1) has arranged a meeting in the Caxton Hall, Westminster, S.W., on Thursday, Jan. 31, at 6.30 p.m., to discuss forensic photography. The opening paper will be by Mr. Henry T. F. Rhodes on the applications of photography to the science of criminal investigation, showing the way in which photographic and photomicrographic methods are applied. On Friday, Feb. 15, at 4 p.m., the Association will meet in the premises of Imperial Chemical Industries, Ltd., at Billingham, Co. Durham, to hear a paper by Dr. A. E. I. Vickers on photography applied to physico-chemical research.

A science meeting of the Colour Group of the Physical Society will be held on Wednesday, Jan. 30, at 3.30 p.m., in the small Physics Lecture Theatre, Imperial College, Imperial Institute Road, S.W. Mr. R. Donaldson will describe a colorimeter with six matching colours, and Mr. T. B. Davenport a direct-reading photo-electric spectrophotometer.

The Association of Austrian Doctors in Great Britain announces that Mr. C. Eisinger will speak on "Recent Advances in Oto-rhinolaryngology" at 69, Greencroft Gardens, N.W.6, on Thursday, Jan. 31, at 7.30 p.m.

A meeting of the Whipps Cross Hospital Medical Society will be held on Friday, Feb. 1, at 8.30 p.m., when Dr. J. Purdon Martin will speak on "Sciatica."

The Torquay Medical Society held its centenary dinner at the Drum Inn, Cockington, on Jan. 17. Sixty members and their guests were present, including the father of the society, Dr. Young Eales, who is 87 years of age and has been a member for 57 years.

Three scholarships for boys are available for entry to the Thames Nautical Training College, H.M.S. Worcester, at the next summer term. They are the Leverhulme Scholarship valued at £125 per annum, the Marine Society Bursary (£70), and the Goldsmiths Company's Scholarship (£50), all tenable for two years in reduction of the normal fees of £140 per annum. Successful candidates will be trained at the College to become executive officers in the Merchant Navy, and applications will close on Jan. 31. Candidates must be between the ages of 15 and 16 years in May, 1946, and will be required to undergo an examination in February. Form of application, specimen examination papers, and copy of the College prospectus can be had from the secretary, Ingress Abbey, Greenhithe, Kent.

The Cecil Joll Memorial Fund has reached the figure of £1,050. The date of closure for subscriptions has been fixed as March 1. The intention of the promoters was to ask the President and Council of the Royal College of Surgeons to establish a biennial or triennial prize essay on a surgical subject.

It has been found necessary to terminate the arrangements made for supplying dried bananas free of cost to persons suffering from steatorrhoea (including coeliac disease and tropical sprue). In future Messrs. Mapleton's Nut Food Co., Ltd., Garston, Liverpool, 19, will supply dried bananas direct to these patients at the rate of 14 lb. per month and at a cost of 9½d. per lb. post free. Applications for supplies should be supported, in the first instance only, by a medical certificate.

As part of the campaign to recruit hospital nursing and domestic staff, the London County Council arranged a public exhibition of its hospital services which is being held at the County Hall, Westminster Bridge, all this week until Saturday at 8 p.m. The general object of this exhibition is to show the various possibilities and attractions of nursing as a profession, particularly in relation to the Council's large range of hospitals and the openings and training available for domestic workers. It includes an information bureau for persons thinking of taking up nursing or domestic work with the L.C.C., and also an interview room for intending candidates.

Dr A. A. McWhan is to retire from the appointment of M.O.H. for Berwickshire on Feb. 14 after nearly 35 years' service in that post, and will be succeeded by Dr Alastair Allan, deputy M.O.H. for the port and town of Greenock.

The Scientific and Technical Group of the Royal Photographic Society of Great Britain (16 Princes Gate S.W. 7) has prepared its fixture list for the present session. Copies may be had from Mr W. F. Berg, Research Laboratories, Kodak, Ltd., Harrow, Middlesex.

Through the Dominions Office, the India Office and the Colonial Office, all Empire and Colonial administrations have been invited to co-operate in making the new *British Pharmacopoeia* now in active preparation, a pharmacopoeia suitable for the whole British Commonwealth of Nations. Mr R. R. Bennett, B.Sc., Harrison Memorial Metallist, told the Pharmaceutical Society in the course of his recent address that preparations which have mainly a local use in particular parts of the Empire will not be included, but supplementary lists of these may be issued locally for local needs. The Pharmacopoeia Commission has exchanged reports and discussions with the Committee of Revision of the *United States Pharmacopoeia* in order to harmonize the titles of both works.

The first of thirteen U.S. Army hospitals bought by U.N.R.R.A. for Poland and Yugoslavia left Newcastle upon Tyne on Jan. 14 for Poland. Eleven are 1,000-bed general hospitals, one is a 750-bed evacuation hospital, and one a 400-bed field hospital. Others are being dispatched from other British ports, and it is expected that all thirteen will have been delivered by the end of this month. They were originally intended to be used in the Far East.

The Minister of Works has appointed Major Gen. R. C. Priest, C.B., to be House Governor of King Edward VII. Convalescent Home for Officers at Osborne, Isle of Wight, in succession to Surgeon Rear-Adm. B. Pickering Pick, C.B.E.

The Privy Council has nominated Dr Bertram A. Young, medical superintendent of St. Alfege's Hospital, Vanbrugh Hill, S.E. 10, to the vacancy on the Council of the Pharmaceutical Society of Great Britain created by the resignation of Sir Walter Langdon Brown on account of ill health.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* an increased prevalence was recorded for whooping cough (324 more cases), measles (206 more), and dysentery (20 more), while 126 fewer cases of scarlet fever and 45 fewer of diphtheria were notified.

Whooping cough, which fell by almost 50% during December, rose throughout the country, the largest increase being London 52. The decline in scarlet fever was general except in the south-western counties, Wales, and the south Midland counties. The largest decreases in diphtheria were Lancashire 24, Durham 22, Warwickshire 11, Northamptonshire 10, the only increases of any size were Nottinghamshire 16, and Suffolk 12. The biggest rises in measles were Lancashire 62, and Norfolk 44, the incidence in the latter county being at the highest level for two years.

Notifications of dysentery in the Melton Mowbray area of Leicestershire increased the size of the recent outbreak from last week's total of 102 to 150. The only other large returns were London 32, Lancashire 24, and Yorks West Riding 12.

In *Scotland* the chief feature was the large increase of 156 in acute primary pneumonia. Small rises were recorded for whooping cough, scarlet fever, and diphtheria, of 13, 11, and 7, respectively. For the third consecutive week a decrease was notified for measles, and this disease is now at the level of last summer. A fall of 28 in the total for dysentery resulted in the lowest number of cases during recent months. The incidence of cerebrospinal fever has been doubled during the past fortnight, 22 of the 34 cases were notified in the city of Glasgow.

In *Ireland* the outbreak of measles appears to be subsiding, 103 cases being recorded during the week. Scarlet fever and whooping-cough were at a low level, but diphtheria remained high with 85 cases.

In *Northern Ireland* the incidence of infectious diseases showed very little change.

Week Ending January 12

The notifications of infectious diseases in *England and Wales* during the week included scarlet fever 1,355, whooping-cough 1,190, diphtheria 525, measles 777, acute pneumonia 1,445, cerebrospinal fever 86, acute poliomyelitis 10, dysentery 344, paratyphoid 2, typhoid 3. In the great towns 165 deaths were attributed to influenza.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 5.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) *England and Wales* (London included), (b) *London* (administrative county), (c) *Scotland*, (d) *Ireland*, (e) *Northern Ireland*. *Figures of Births and Deaths, and of Deaths recorded under the category of Infectious Diseases*: (a) The 126 great towns in *England and Wales* (including London), (b) *London* (administrative county), (c) The 16 principal towns in *Scotland*, (d) The 10 principal towns in *Ireland*, (e) The 10 principal towns in *Northern Ireland*.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

Disease	1946					1945 (Corresponding Week)

Stillbirths	217	20	34			224	20	25		
Rate per 1,000 total births (including stillbirths)			36					25		

* Measles and whooping-cough are not notifiable in *Scotland*, and the returns are therefore an approximation only.

† Includes primary form for *England and Wales*, *London* (administrative county) and *Northern Ireland*.

‡ Includes puerperal fever for *England and Wales* and *Ireland*.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Athology Westcent*, London. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent*, London.

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Mediscra Westcent*, London.

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Toxic Effects of High Octane Petrol

Q.—Is anything known about chronic poisoning with high octane spirit? A patient who drove a petrol lorry for three years and was constantly exposed to fumes, sometimes having to step back to avoid being overcome during filling operations, is now in bed with pains in the back, epigastric fullness, gross hypertension, and severe retinitis. Urine shows no albumin or other abnormality; urea clearance 70% normal; no gross abnormality in the blood count. Is the present condition likely to be connected with the petrol? Would any other tests be useful, and is there any treatment?

A.—While little is known about chronic poisoning from octane spirit, it is certain that octane is more acutely toxic than petrol of lower specific gravity and boiling-point. Among the disturbances following chronic exposure to petrol fumes are listed: headache, vertigo, lack of concentration, respiratory disorders, loss of corneal reflex, tremor of eyelids, paraesthesiae of the hands, increased knee-jerks, chronic polyneuritis, and nephritis. Neither in chronic poisoning nor in the sequelae of acute or subacute poisoning (the last may perhaps be applicable to your case, since the man had on occasion "to step back to avoid being overcome") has hypertension or retinitis been recorded, but blurred vision and burning pain in the chest and upper abdomen have been observed in the milder forms of acute poisoning, and after recovery from acute narcosis caused by petrol fumes. Two such cases, after heavy exposure to high octane petrol, have recently been described by J. S. Lawrence (*Journal*, 1945, 1, 871). It is unlikely that the hypertension and retinitis are due to exposure to petrol, but it is possible that the patient's general condition and gastro-intestinal disturbance have been made worse by it. In view of the fact that permanent damage to the central nervous system has followed acute poisoning—in the form of petechial haemorrhages in the brain, meninges, and spinal cord—it might be as well to have a thorough examination of the nervous system. So far as is known, no special treatment is indicated.

Keeping Properties of Serum and Plasma

Q.—What are the keeping properties of human citrated plasma and dried human serum? How long after the date of issue is it safe to use them? I have a stock of human plasma in sodium citrate solution dated Feb. 4, 1942, and a stock of dried human serum dated June 1, 1941.

A.—Human citrated plasma in liquid form should not be stored unless frozen in the solid state. Plasma dated 1942 should certainly not be used. Dried preparations of either serum or plasma, so far as is known at present, keep indefinitely. There is no reason to suppose that dried serum dated 1941 would be unsatisfactory. Better preparations are now available, however, as technical procedures have been improved. Adequate supplies of a later date are plentiful.

Duration of Breast-feeding

Q.—It is customary in our civilized world to advise breast-feeding a baby for nine months. As a baby goes on to mixed feeding and cuts teeth before that age, how long did Nature intend the baby to be breast-fed before civilization?

A.—The answer is anybody's guess. But it is clear in the animal kingdom that a period of mixed feeding, in the double sense, does exist after the young begin to lap or chew solid food, and the mother's supply is neglected once enough food and drink can be obtained from other sources. It is said that many uncivilized tribes (in Africa) continue breast-feeding for a long period, and even the child of school age "takes a pull," so to speak, from time to time. Whether Nature intended this or not is another matter. It seems reasonable to assume that the arbitrary period of nine months has some custom behind it, and, in general, breast-feeding in the second year of life was probably never intended.

Treatment of Goitre

Q.—What is the best treatment for a girl of 16 who has been suffering from a goitre, which enlarges just before each menstruation, for the past four years? Iodine has been tried, but it increased the size of the goitre. The basal metabolic rate cannot be done in this part of the world (Bengal). Would gonadal hormone treatment be of any use? Is there any danger in trying thiouracil before taking the basal metabolic rate? The girl is 5 ft. 2 in. (1.57 m.), weighs 9 st. (57.15 kg.), and her average pulse rate is 90. She is nervous, but otherwise healthy. Her finger-nails have not had to be pared for the last year, but are healthy in appearance, though her toenails have been unusually hard since childhood.

A.—It is common for a simple goitre to begin at puberty and to show an exacerbation before each menstrual period. Before deciding upon treatment it is necessary to determine whether or not hyperthyroidism is present. Though a B.M.R. estimation is useful, the decision can be made on clinical grounds. Is the girl anxious, "highly strung," and excitable? Is her skin flushed, damp, and unduly warm? Does she feel the heat excessively? Has she lost weight? Is her resting pulse rate high? Is the pulse pressure high? Does she suffer from breathlessness on slight exertion or even when embarrassed? Are ocular signs, such as lid retraction, exophthalmos, or the classical signs of Graves's disease, present? Is there in any part of her body an obvious sympathetic predominance?

Some of these questions are already answered. She is not emaciated; in fact she is rather plump. But is her weight increasing or decreasing? The behaviour of the nails is not characteristic, but is, perhaps, more suggestive of thyroid underactivity than of overactivity. Her "average" pulse rate is rather fast, but as it is not a resting pulse rate the circumstances in which it was taken must be considered before it is interpreted. She may have been in the habit of hurrying to her consultations, or she may be frightened of doctors. Her nervous temperament may be due to causes other than hyperthyroidism, and the fast pulse rate may be a reflection of these rather than of thyroid disorder.

On the whole one would be inclined to guess that no hyperthyroidism is present. In this case thiouracil should not be given, for it is not a safe remedy. Though it is difficult to produce myxoedema in a patient with a functionally normal thyroid, it is not impossible. Moreover, a daily watch on the white corpuscles is essential if all risk of agranulocytosis is to be avoided. The treatment of choice is desiccated thyroid. Iodine is often effective, but has already failed in this case, probably because the thyroid is incapable of turning it into thyroxine. It is best to begin with a dose of gr. 1/4 (16 mg.) of thyroideum siccum every morning, and to increase the dose very gradually at fortnightly intervals, watching carefully for signs of overdosage, especially loss of weight and tachycardia. The final dose will be that which improves the goitre without producing such signs. No gonadal hormone will do any good at all.

Should further consideration, on the other hand, lead to a diagnosis of hyperthyroid goitre, thiouracil should certainly be used, in combination with physical and mental rest. With a dose of 0.4 to 0.6 g. daily there is little risk of an increase in the size of the goitre. When the condition of the patient suggests that improvement has set in, which is usually after two to four weeks, the dose is reduced to 0.2 g. daily, and after a few weeks to 0.1 g. A close watch on the white cells must be maintained throughout. In hyperthyroidism also gonadal hormones are useless. There is a theoretical reason for giving oestrogens, for they produce pituitary depression and might therefore be expected to reduce the output of thyrotrophic hormone. Unfortunately, they don't work.

Incompetent Lacrimal Duct

Q.—About ten years ago a man had an antristomy done. For the past five or six years he has suffered from the following trouble: If, during a cold, he blows his nose, mucus is driven back through the naso-lacrimal duct into the eye. When driving in a wind there is an inadequate drainage of tears, which flow on to the cheek. Why is this, and what is the treatment?

A.—The lower end of the lacrimal duct must have been damaged at the operation in making an opening between the antrum and the nasal fossa, and the valvular mechanism has been rendered incompetent. The only radical treatment would be to make a direct communication between the lacrimal duct and the nose (rhinodacryo-cystostomy), as for stenosis of the lacrimal duct, but it would be impossible to guarantee that this would give complete relief.

Morphine Dosage

Q.—In cases of severe colic—intestinal, renal, or biliary—and also in anginal and other severe neuralgic pains, what is the usual, and also the maximum, dose of morphine that can be given hypodermically with safety? How often, and at what intervals, can it be repeated?

A.—The usual dose of morphine is 1/4 gr. (16 mg.). Several cases are known in which a dose of 1 gr. (65 mg.) has proved fatal to

adults. It is therefore rarely wise to inject more than 1.2 gr. (32 mg.) within a short interval of time. It may sometimes be two hours or longer before the morphine exerts its full effect. This is particularly likely to happen in patients who are shocked and collapsed. At first they do not absorb the morphine from the site of injection, and later they may display delayed morphine poisoning when the circulation rallies and the drug begins to act. Under normal circumstances most of the effects of 1/4 gr. will have passed off in six to eight hours, and it would therefore be safe to give 1/4 gr. (16 mg.) every eight hours. In disease the physician must decide whether persistent pain is due to resistance to morphine, in which case a larger dose would be indicated, or to failure of absorption, in which case further administration might be disastrous. It is therefore not possible to make a dogmatic statement, though as a general rule it is safe to give an initial dose of 1/2 gr. (32 mg.) morphine, and follow this by 1/4 gr. (16 mg.) in two or three hours in the severe type of pain which occurs in coronary thrombosis.

Acute Cardiac Failure

Q.—What are the best emergency heart stimulants for acute cardiac failure in (a) chronic myocarditis the result of chronic valvular disease or coronary thrombosis; (b) acute myocarditis resulting from infections, such as pneumonia, typhoid, etc.? Is nikethamide a cardiac centre stimulant or, as some authorities seem to indicate, does it act only on the respiratory centre?

A.—Only general indications can be given in answer to this question; the details of treatment will depend upon the appraisal of the exact clinical state. In acute failure due to chronic valvular disease auricular fibrillation is likely to be present, and if the patient is not already digitalized this should be undertaken by one of the rapid methods, such as tr. digitalis 1½ dr. (5.25 c.cm.) at once, followed by 30 min. (1.8 c.cm.) six-hourly until the heart rate drops to the region of 100 per minute, after which 30 min. (1.8 c.cm.) thrice daily will probably suffice. In acute failure after coronary thrombosis digitalis is less likely to be beneficial. Nikethamide is commonly effective empirically, though its mode of action is not fully understood; 2 to 4 c.cm. should be given intramuscularly. Acute myocarditis in the course of pneumonia or typhoid must be far from common; the acute failure which may develop in these diseases is peripheral, and not due to inflammatory or other lesions in the heart muscle. Such peripheral failure is caused by toxæmia, often with dehydration, and the treatment will be directed to the relief of these states. Fluid infusions of 5% glucose in saline may therefore be necessary (intravenous or rectal) if the patient cannot take sufficient by the oral route. Nikethamide 2 c.cm. intramuscularly four-hourly, or strychnine gr. 1/32 (2 mg.), repeated if necessary, may help.

Dimethyl Phthalate as Mosquito Repellent

Q.—Is dimethyl phthalate a reliable mosquito repellent, as a lotion or as an ointment?

A.—Dimethyl phthalate is certainly a very effective repellent for mosquitoes and several other biting insects. It is a colourless oily liquid and is used undiluted. A few drops rubbed on the hands are wiped over the face or other areas of skin to be protected (avoiding eyelids and lips, etc., which are somewhat irritated by the liquid). This protection lasts for several hours until washed off by perspiration, etc. Another method of use is to apply the liquid to garments, through which some mosquitoes will bite. Applied in this way the repellent lasts for a week or so. Care must be observed, however, as the liquid dissolves certain types of artificial fabrics. It is harmless to silk, wool, and cotton (see our annotation, May 19, 1945, p. 705). We understand that supplies are available in small quantities in this country.

Chromidrosis

Q.—A case of trichomycosis of the axillary hair with red coloration of the sweat has relapsed twice—once after shaving, and once after shaving and treating the area with 1 in 4,000 perchloride of mercury in spirit. Would you advise as to treatment and prognosis?

A.—Chromidrosis is sometimes faked in hysterical subjects, or may be due to bacterial infection, such as *B. prodigiosus*. Treatment of this rare condition is often disappointing, and should take into consideration both the general health and the nervous system. It should not be forgotten that reinfection from clothing explains the tendency to recurrence in some instances.

Induction of Labour by Quinine

Q.—Is there any danger to the foetus in drug induction of labour by quinine 10 gr. (0.65 g.), 5 gr. (0.32 g.), 5 gr. (0.32 g.), at two-hourly intervals? In two successive cases the newborn infant died in hyperpnea on the second day, but this may have no special significance.

A.—Quinine given to the mother before or during labour permeates the placenta, enters the foetal circulation, and can be recovered from the urine of the child at birth. It can also be demonstrated in the amniotic fluid. It is therefore reasonable to suppose that it may have

a toxic effect on the foetus. Several writers and many clinicians have noted that after the administration of quinine, in the sort of dosage mentioned above, the foetus is prone to pass meconium during labour, and it sometimes dies *in utero* for no apparent reason—other than exposure to quinine. As a result of extensive clinical and pharmacological investigation of 805 cases of quinine induction, W. J. Dilling, A. A. Gemmell, and Eileen S. Sadler (*J. Obstet. Gynaec. Brit. Emp.*, 1929, 36, 352; 1930, 37, 529) concluded that 6 foetal deaths (0.75%) were probably due to the quinine, and another 11 deaths (1.36%) were doubtfully caused by it. However, they pointed out that an equal number of unexplained foetal deaths occur in any series of normal labours in which quinine is not administered. Therefore it has not yet been proved scientifically that quinine can cause foetal deaths. Nevertheless, as a result of clinical experience, most obstetricians are convinced that quinine does sometimes kill the child. Some believe that it can have other non-fatal ill effects, such as damage to the auditory nerve. The majority, therefore, rarely use quinine in an attempt to induce labour except when the foetus is already dead, and this type of induction is hardly ever practised now in many of the large maternity hospitals.

Even though it be accepted that large doses of quinine can kill or harm the foetus *in utero*, it remains doubtful whether it can cause neonatal death. The period of greatest danger—i.e., when the concentration in the maternal and foetal tissues is at its highest—is 6 to 12 hours after the first dose of quinine. Quinine sometimes persists in high concentration in the foetal tissues for a much longer time than in the maternal, and it has been identified in small amounts in foetal and placental tissues even 80 hours after the first dose. Although it is right to suspect that quinine may have been responsible for the deaths of these two babies, it is unjustifiable to come to any conclusion unless post-mortem examinations were carried out.

Sensitivity to Soap

Q.—A patient has had attacks of dermatitis affecting the face, hands, and arms for about two years. So long as she does not use soap she is quite free from dermatitis. Will she ever be able to use soap with impunity, and is there any method of treatment that would help to make her skin insensitive to the effects of soap?

A.—This patient's skin may be sensitive to one or more of the ingredients of soap. If it was toilet soap that caused the first attack it is unlikely that free alkali was the original irritant, which might have been either the perfume or a sodium salt of a fatty acid. If, however, the original attack was traced to the use of a household (including "soft soap") or medicated soap the possibilities are wider. A trial might be made of the patient's skin reaction to the use of a non-scented shaving soap, which might be tolerated. There is always the possibility if soft, or softened, water is used for washing that the soap lather is not being adequately rinsed off, and this may be the cause of the skin irritation. If this is the case a rinse of a weak solution of magnesium sulphate would assist in the removal of the soap from the skin.

INCOME TAX

Deductions for Use of a Car

Changes in the income-tax code are usually effected by means of the yearly Finance Acts, but last year a special Act—the Income Tax Act, 1945—was passed which will materially affect the deductions that can be claimed by those who own and use "plant and machinery" for trade or professional purposes. So far as the medical profession is concerned, "plant and machinery" is represented in the main by the car, or cars, used in the work of the practice or for carrying out the duties of a medical employment. By Section 18 of the Finance (No. 2) Act, 1945, the relevant provisions of the earlier Act are brought into force as from April 6, 1946. Accordingly the changes made will affect the calculation of profits, or of the net earnings of employment, only as regards periods beginning on or after that date. Practitioners assessed under Schedule D, on the usual basis of the profits of the previous year, will find that it does not make any difference to the tax payable for 1946-7; but it will affect individuals assessed under Schedule E on the current year's basis. Even in the latter case it seems unlikely that any definite and effective claims can be made on the new basis until the position is known for the whole of the year to April 5, 1947. The changes made may be summarized briefly.

(1) A new allowance called an "initial allowance," is instituted, the amount of which is 20% of the capital expenditure, and this is to be treated as if it were an expense of the year in which the cost was incurred. For instance, if a practitioner bought a car for professional use at a cost of £500 on Nov. 1, 1946, he would become entitled to a deduction from his profits or earnings of £100 (20% of £500) in reckoning his professional income for a period which includes that date. The "initial allowance" will be deducted, as the present "depreciation allowance" is now, in arriving at the written-down value on which the depreciation allowance is calculated for a subsequent year. The allowance will also be given in respect of a car bought on or after April 6, 1944, but will be treated as

if the transaction had taken place on or after April 6, 1946, and will therefore not ordinarily affect tax due under Schedule D for 1946-7, though ultimately it will affect tax due under Schedule E for that year. Any allowance for a car bought before then will be subject to an appropriate restriction if depreciation has already been allowed on the full cost before deducting the initial allowance.

(2) (a) The legal basis for calculation of the annual allowance is altered—though the new basis was in fact already in common use. The calculation is to be made not, as is legally the case at present, according to what car or cars may be owned and used during the year of assessment, but according to the position as at the date of the end of the year which forms the basis year for the assessment. Thus, if a practitioner has a car of which the written-down value on Dec. 31, 1945, was £250, it is on that amount that the depreciation allowance for 1946-7 must be calculated, even though he may have sold that car and bought another early in 1946. (b) The present method of calculating the annual allowance is unnecessarily complicated. In the first place a percentage, say 20%, is fixed which is regarded by the District Commissioners (or Special Commissioners) as reasonable, and to the amount so calculated an addition of one-fifth is made to arrive at the income-tax allowance. For example, if the written-down value of the car in question is £300, the depreciation allowance will be £60 (20% of £300) plus £12 (one-fifth of £60), making a total of £72. But in making the deduction from £300 for the purpose of the next year's calculation the £60 would be deducted but not the £12, and the figure carried forward would be £300 less £60—i.e., £240. In future one-fourth will be added to the percentage figure and the total allowance will be deducted in the "written-down" record. Thus, in the example above the allowance will be £60 + £15 = £75, and the capital figure to be carried forward will be £300 - £75—i.e., £225.

(3) The new provisions establish what are called "balancing allowances" and "balancing charges." They have been devised to meet criticisms of the present arrangements arising from the fact that the taxpayer often finds himself left with an ultimate loss on some machinery or plant for which he receives no income-tax allowance. If, for example, a car is replaced by a somewhat similar one after some years of service, the present "obsolescence allowance" gives equitable relief. But that allowance has two conditions, or rather a condition and a restriction: the car for which the obsolescence allowance is claimed must be replaced, and the amount of the allowance must not exceed the cost of the new car. A practitioner retiring from professional work is debarred from the allowance because he does not replace the car for professional purposes; and where the cost of the new car is much below that of the one replaced—if the latter had been bought at a scarcity price or the former were bought second-hand—only partial relief is forthcoming in respect of the loss on the old car. Under the new system a balancing allowance will be given whether the car is replaced or not, and will not be restricted by reference to the cost of the new car, if there is one. On the other hand, if the car is sold for a sum which when added to the amounts allowed in respect of it by way of "initial allowance" and depreciation exceeds its cost, the Revenue has the right to bring the "profit" into taxation as a "balancing charge." It seems not unlikely that there will prove to be a good many cases of this kind, where cars bought at something like pre-war prices are sold after April, 1944, but that is a temporary price which some taxpayers will have to pay for a general and permanent gain.

LETTERS, NOTES, ETC.

Nocturnal Cramp

Dr. E. LUDOWICI (Sydney, N.S.W.) writes: With reference to the question and answer on nocturnal cramp (Aug. 18, p. 240), this condition can be very troublesome. I have found that an increased amount of salt taken in the diet will avert the attacks: for the attack a quarter of a teaspoonful in water followed by a little sherry and an A.P.C. tablet is effective; extension of the leg and foot also helps.

Operations for Varicose Veins

Dr. R. K. BROOKS (Chipping Sodbury) writes: As a victim of this complaint and wondering what will eventually be my own fate, I had ample opportunity to study the subject during the war years. It was my privilege to be the M.O. to soldiers, about a company strength, throughout the war. During this time there were four changes of regiments and frequent changes of men, and so my observations were not restricted to one group of men whose category was B or C. A foot inspection or the customary F.F.I. would reveal an interesting assortment of end-results of attempts to treat varicose veins. In my opinion—and I have no hesitation in saying it—these were all failures. Whether it was the injection method, or ligation, or complete removal of the vein, all methods were unsatisfactory, and I was convinced that there was no satisfactory method of surgically treating varicose veins. The best one can do is to support the engorged vein with something like elastic stockings. A varicose vein is, after all, the normal penalty (physiological) for a two-legged animal who is getting old and is obliged to spend an

excessive number of hours on his feet. If this is so, it stands to reason that if you ligate the one vein, or produce a sclerosis, or even remove the vein, you are only hastening the varicosity of other veins in the neighbourhood. Is one better off in the end? Now, no doubt this reasoning will evoke the wrath of surgeons, but can they offer a guarantee or a better reasoning for not withholding surgical interference?

Bite of *Culex molestus*

J. T. S. writes: Should the question put to you (Nov. 10, p. 675) resolve itself in non-technical language to "Can you stop a mosquito bite from swelling and itching?"—I may be of assistance. I have lived in several parts of the world infested by mosquitoes, and have found the following simple treatment effective on myself and a large number of other people. As soon as possible after bites are noticed, scratch them half a dozen times with a fine, sterilized needle (I have merely held it in a match flame) and apply tincture of iodine. The itching stops instantly with the counter-irritation of the iodine, and the swelling and general effect of the bite disappear in about 12 hours. I cannot say whether this would help your correspondent's patient, but I have never known it fail. Obviously, the quicker the remedy is applied the quicker the cure.

Applying for a Hospital Appointment

Mr. A. WALLIS KENDALL, F.R.C.S., writes: Surely it is possible to avoid asking candidates for hospital appointments for such large numbers of copies of their applications; as an example, in an advertisement this week sixty copies are required. A copy of each application could be displayed in the medical staff room or could be circulated. By either or both methods sufficient opportunity would be given to all members of the honorary staff to gain the necessary information about a candidate before the usual personal interview. Again, the natural desire to please the electing committee leads to a competition in the elegance of production of the applications, with a great deal of expense for printing to candidates who as a class are not usually overburdened with riches. If type-written copies were asked for they would be quite adequate. Lavish demands for copies are such a certain sign of a return to peacetime conditions that it may seem a little ungracious not to welcome them. I have in mind, however, the words of the poet:

"War lays a burden on the reeling State,
And peace does nothing to relieve the weight."

British Medical Literature: Europe's Need

Dr. LADISLAV FISH writes from 5, Gurney Drive, London, N.2: U.N.R.R.A. supplies the liberated countries with drugs, instruments, hospital equipment, but nobody supplies them with books, medical literature, etc. In my experience this need is equally as important. There is no planning with regard to this, although the need is urgent—for example, it is vital for Czechoslovak medical science and practice to be in close contact with medicine of a nation whose language opens the door to the world. It greatly concerns this country, and it is in her interest that the vacuum created by the disappearance of German medical literature should be filled with British.

My experience during my work in Czechoslovakia (where I went with the 1st Czechoslovak Medical Mission from this country) includes the following. German medicine had a very great influence in Czechoslovakia before the war, and this influence changed during the occupation into complete domination. After the German defeat German periodicals and other literature disappeared, but their influence remained. The sources of information, references, etc., in published papers are mainly if not entirely German. Students, in spite of their disgust, have to study from German books because there are no others. The few older Czech medical textbooks are copied and cyclostyled by the students, who often find only a single remaining copy in the library. It is not always easy to introduce the newer methods and views in medical science and practice. The strength of German influence and its persistence become apparent in a reluctance to accept anything new or different even when the old is doubtless inferior. To change this it is necessary to supply the profession with plenty of reading material which would give enough information regarding the advances and experiences of other nations. This is a great chance for British medicine to widen her publicity. It would be too costly and difficult now to set up a central organization for the purpose of supplying the universities, libraries, etc., but I would like to suggest starting in a modest way—e.g., that the societies of the various specialties should supply reference books, periodicals, etc., both new and old, to the university department of the same specialty. As an E.N.T. surgeon I would like to appeal to British oto-laryngologists to collect a small library (not necessarily composed of new books, but mainly recent editions from the last 10 years) for the E.N.T. Department of the Charles University of Prague. It needs them urgently, and the teaching staff, assistants, and students would appreciate them greatly. Anybody who will give a book for this purpose can be certain that it will be an excellent contribution not only to Czech medicine but also to the mutual understanding of nations.

PSYCHOLOGICAL REACTIONS IN SOLDIERS TO THE LOSS OF VISION OF ONE EYE, AND THEIR TREATMENT

BY

P. M. DUKE-EIDDER, M.B., B.S.

AND

E. WITTKOWER, M.D.

The loss of one eye is not in itself a severe disability, yet, more often than is generally known, individuals who have lost an eye are unduly distressed about their defect and feel themselves handicapped in numerous activities out of proportion to their actual disablement. Their handicaps are in the main not anatomical in origin, but are due to what is commonly described as a functional overlay. The circumstances of war have given us the opportunity of coming into contact with numerous men who had recently lost one eye, functionally or in fact, and provided us with ideal conditions in which to study their reactions, and since, apart from war, the same reactions to a large extent are met with in civilian life, their record may be of not without interest. For the purposes of this study an unselected sample of 102 one-eyed soldiers was taken, of the following composition:

- 1 Disability—Eye diseases, 39, eye injury 63. Eye removed, 29, eye retained, 73.
- 2 Rank—32 N.C.O.s, 70 privates or equivalent.
- 3 Type of Enlistment—11 members of the Regular Forces, 14 Territorials, 19 volunteers, 58 conscripts.
- 4 Age—Varying from 19 to 53.
- 5 Marital Status—67 married, 35 single.
- 6 Attributability—Injury attributable to enemy action, 19, injury not attributable to enemy action, 83.
- 7 Duration of disability.

26 men were seen within six months of the onset of their eye disease or within six months subsequent to their eye injury.

15 men were classed as having subchronic, chronic, or recurrent eye diseases (still or again in a florid state).

61 men had been blind in one eye as a result of eye disease or of injury for at least six months. The latter were regarded as permanently blind in one eye.

Emotional Reaction to Monocular Eye Injury and Disease

Eye Injury.—Men who sustain a serious injury to one eye in an accident or in battle rarely lose consciousness immediately. In many cases they see a flash and feel the impact of the shell fragment like a blow from a boxing glove or like being struck by a sledgehammer. Instinctively they raise their corresponding arm in self defence. Sometimes they are completely blind for a time, sometimes in the heat of the battle, their injury remains almost unnoticed, and only blood trickling down the cheek or dropping on to their arm indicates what has happened. On arriving at the hospital a sense of relief commonly prevails; after all, it is good to be alive, they are really lucky, and it could have been much worse. Their hopes and fears rise and fall with the prognostications of their medical officers, and where excision of the eye is deemed necessary depression is usual. Lying in bed in hospital they think of their occupational prospects. As they now are their old firm may not take them back. Will they be able to support their families? It is true that they can still see, but will the other eye be affected? If so, this would mean blindness, uselessness and dependence on other people for the rest of their lives. The first look in a mirror gives them, almost invariably, another shock. But in

general they are sustained by the spirit and atmosphere of the hospital, and overriding all other considerations there is the desire to get home as quickly as possible.

Eye Diseases.—A man with an acute affection of one eye is rightly or wrongly usually attributes his disability to a strain, a blow or a cold. On admission to hospital he either dismisses the eye trouble lightly heartedly, trusting implicitly in the skill of the ophthalmologist, or he is alarmed about the possibility of its being something serious. Absence of pain, no outward appearance of disease, and iridodilator onset allayed the concern of his doctor, arouse anxiety, but encouraging remarks by doctors and nurses dispel these mutual fears. Much depends upon the doctor's attitude. If the eye specialist expresses any doubt about the full restoration of vision, dormant fears regarding blindness are greatly accentuated, and if the verdict is passed that the loss of the one eye is inevitable these fears assume quite unreasonable proportions.

In chronic cases, if after many months or even years of careful medical attention the condition deteriorates or shows no visible signs of improvement, the man is affected, as a general rule, in two extreme and contrasting ways which depend on his personality. He either hopes for the best or the best of his past experiences, or he expects the worst, regarding any relief as a further threat to his vision. Hope of complete recovery is then abandoned and the much-dreaded blindness no longer a vague possibility, looms before him as almost inevitable. Whether or not this fear is justified he prepares himself mentally to lead the life of a blind man.

Emotional Reaction to Permanent Blindness in One Eye

After the initial emotional crisis has abated few one-eyed men recover their emotional balance completely. Of 61 men in this series who were seen at a time when they had passed beyond their early mood fluctuations only 9 were in no way or but little emotionally perturbed by their disability. Among these 9 were 5 unimaginative stable dullards, not easily upset by anything. Five other men adopted an attitude of defiance towards their disability, mingled with a tendency to sulk off what they could do in spite of it. They soon learned to play games and to shoot from the shoulder corresponding to the good eye. The remaining 47 men showed evidence of understandable but irrational and therefore morbid fears concerning their social relationships, the future economic security of dependants, and the possibility of further harm to themselves. Their reactions may be classified thus:

(a) Social Anxiety (26 Men)

Depressive.—An eye affection is quickly noted. Children point at the one-eyed man and call him names. A well-meaning neighbour remarks on his hard luck and he is subjected to some good natured chaffing. If his employment is still discharging he may be repugnant to some people, but if he has a well-fitting artificial eye he is rather greatly handicapped in his working efficiency, not particularly conspicuous in appearance. Rich or poor, wrongly, wrongly, of an artificial eye commonly believe that it is too big or too small, too

glaring, too sunken, or too protruding. To some the concealment formerly provided by an eyeshade was preferable to the imperfect camouflage of the artificial eye. They complain that the winking of the eye invariably draws the attention of people and that to take the eye out in the presence of others is very embarrassing. In extreme cases the effect of their disability upon their relation to others becomes a main preoccupation. They dare not look anybody straight in the face. If they are addressed they get flustered. In the company of their friends they are not too uneasy, but to face a group of strangers fills them with terror. Repelled by their appearance, they say, people in a restaurant move away, get up, or walk out. At dances girls refuse to dance with them. Unable to stand their ordeal any longer, men of this group cut themselves off from their social contacts. "I don't fit in," they say, or "I am out of the picture and not wanted."

Resentful—Another group of men, instead of worrying inwardly and evading contact with a world now believed to be hostile, react with active and vociferous resentment. Their social anxiety has been converted into a violent protest against society in which accusations and condemnations feature prominently. Some of them simply become bad-tempered and cantankerous and "flare up" at the slightest provocation. "Words come out of my mouth which I don't really mean," said one man. These men quarrel with their friends, they are no longer capable of "taking" a joke, they hit out furiously, but more in the metaphorical than in the physical sense. Some of them threaten to use violence, and a few actually do, and as they lose one friend after another through their vicious temper they gradually drift into social isolation. Men of this type are usually disgruntled about the employment given to them after their disablement. In their opinion one-eyed men should be specially catered for. If their work does not suit them they report sick or become troublesome, losing all interest in their job and making no bones about their desire to get out of it. They believe that they would be far better off in some other sphere of activity, but view their future with gloom and bitterness, yet one main interest remains—their determination to put up a fight for a pension.

(b) Anxiety over Dependants (10 Men)

A defect of the eye impairs a working-man's earning power. Certain occupations are barred to him and some firms are reluctant to employ him. Hence a certain number of married men are seriously concerned about the effect which the loss of an eye may have on the security of their dependants. Within justifiable limits, or going far beyond them, they are afraid that they will be unable to discharge their obligations towards their families.

Members of this group were diligent, conscientious, reliable, and persevering workers before their injury, efficient and of good morale. Perhaps after a hard struggle they had managed to build a reasonably secure livelihood for themselves and they had settled down to married life. At hospital they were anxious to leave at the earliest opportunity, and on return to their old environment they carried on to the best of their ability irrespective of whether they liked the job allotted to them or not. To all appearances they had changed very little. But if the conversation were allowed to flow freely they almost invariably revealed a dread of how they would get on in civilian life. The Army gives them financial security, but this is temporary, and the thought of leaving it is an ever-present worry. "I may not be able to support my wife after the fashion I would like to," said one of them, "will I be able to give my children as good an education as I intended to, in my present state of physical fitness? Will I be able to make the money to look after them? The whole future of my family depends on my eyes." Intent on preserving what earning capacity is left to him, a man of this type, whose greatest need is security, avoids all potential dangers to the remaining eye. He keeps out of sport, reads as little as possible, does not frequent the cinema any longer, and guards his eyesight jealously. The fear haunts him that the other eye may become affected, that he may go blind, and that if this should happen he will become useless.

(c) Self-centred, Self-pitying Anxiety (11 Men)

Complaints of headache, of difficulty over judging distances, of eye-strain, of photophobia, and of night-blindness are common in one-eyed men. Of these complaints, difficulty over judging distances at hand is sufficiently explained by the nature of the defect, which owing to the need for adaptation to monocular vision, also counts for headaches and "eye strain" within some six months of the disablement. There is no physiological reason for a continuation of such symptoms beyond this period. These complaints vary in intensity and in descriptive quality. According to the colourful accounts of some of the men such difficulties seem to incapacitate them more or less completely. Their headaches—described as "terrible" or "colossal"—come on whenever they attempt work. "Any close work is pretty hopeless"; "I have to feel for things before I pick them up"; "I can't distinguish between an insect near or a bird far away"; "The good eye becomes tired easily, smart, and aches a lot"; "After half an hour's reading or writing

it gets all mixed up", "Sunlight is very dangerous to me," they say. If the sun is out they wear dark glasses or gaze on the ground. Another pair of spectacles is worn against the "harmful" effect of wind. They are "absolutely hopeless" in the dark and have to be led about. Without assistance they grope their way along or progress by feeling their way with one foot along the edge of the kerb.

In addition, most of these men are troubled by general complaints—dizziness, heart trouble, indigestion, and so on, they become easily fatigued, sleep badly, their memory has failed since the injury, and they are unable to concentrate on anything. Surely, they feel, anybody can see how ill they are, but no one will take it seriously. As in the previous type, but for different reasons, an all-pervading fear about further injury to themselves dominates their thought and actions. They have taken full flight into dependence and illness without even trying to take up the fight against their real external difficulties, which undoubtedly exist. Fear of going blind, so common in one-eyed men, assumes in them quite grotesque proportions. They do not go out during the daytime because the sun may do harm to their good eye, and they do not go out at night because they may bump into something. They do not play any game because the ball may hit them in the eye, and they do not read or go to the cinema because the strain may be too much for them. A little boy using a catapult or throwing a paper aeroplane up into the air frightens them out of their wits.

Factors Determining the Emotional Reaction

The type of emotional reaction to the loss of an eye is determined by three main factors: (1) previous personality, (2) nature of the disability, (3) nature of employment.

(1) *Previous Personality*.—Comparison between reaction types and previous personality types allows the following conclusions:

Minor or No Emotional Maladjustment.—A constructive-defiant attitude towards their disability, devoid of undue anxiety, was displayed by men of the conscientious personality type. Of those labelled as "resigned," only one had an eye excised.

Social Anxiety.—The depressive group is largely composed of men who have always been shy, self-conscious, and retiring, afraid of making themselves conspicuous and of being held up to ridicule (9 out of 14). They needed praise as a means of self-assurance and were easily snubbed. The advent of their disfiguring eye affection had tipped the balance of their emotional scales. Men who were *resentful* in their reaction derived from two different personality types, about evenly distributed. Prior to their eye affection they were either simple-minded, uneducated, blunt, outspoken, fond of drinking and gambling, and enjoyed a good "scrap," or they were intelligent, educated, and ambitious, and therefore bitterly disappointed in consequence of the frustrations imposed upon them by their disability. (The effect of uncongenial employment is dealt with below.)

Anxiety over Dependants.—With two exceptions, as already pointed out, this type of anxiety was found to occur in men with a severe—perhaps over-severe—sense of duty. They were hard workers, meticulous in attention to detail, sticklers for punctuality, and in general fully appreciative of their responsibilities and obligations. They had always kept an eye on the future, had saved some money for a rainy day, and had always been greatly concerned about their financial security and the security of those dear to them.

Self-centred, Self-pitying Anxiety.—Previous characteristics, such as over-dependence, timidity, and childish *amour propre* may have foreshadowed their self-pitying reaction to their disability in four men of this group. The others did not conform to any specific type.

(2) *Nature of Disability*.—Comparison of the reaction type with the nature of the disability shows that the removal of a eye predominantly disturbs the social relationships of an individual, engendering social anxiety, whereas retention of the blind eye predominantly rouses anxiety over dependants and over further injury.

(3) *Nature of Employment*.—After discharge from hospital the one-eyed soldier proceeds to a convalescent depot, where he is posted to a training depot. There, as a result of inevitable administrative delays, he remains for several weeks until his disposal has been decided. He is then posted to a unit where again, quite often for a period of several weeks, little use is made of him. To keep him busy he is usually employed on fatigues and odd jobs, and by the time the nature of his employment has been finally settled his morale is apt to be low. On the other hand, if the new job is to his liking his morale improves. Some men, however, are frequently moved either within their own unit or between different units because a suitable job is not readily available, or because of their constant refusal to undertake duties for which they feel themselves

the psychological distress of mutilation are essential. In those who are fit these ends are attained by physical training exercises in which, in addition to toning up the system generally, special attention is paid to re-educating the sense of equilibrium and the judgment of distances by means of parallel bars, jumping, and balancing exercises; this is implemented by organized games out of doors, particularly ball games, which are rapidly stepped up in speed, and organized indoor games such as ping-pong and billiards. The more sedentary part of the day is spent in occupational therapy; this can be of great value, the best results being obtained by weaving on a big loom and the performance of other tasks involving rapid and fine co-ordination between eye and hand."

Position in Industry.—The position of one-eyed workers in industry varies a great deal. Some firms employ one-eyed men with good success. They prove themselves efficient at most jobs, even in the metal and engineering trades. Their accident record is good; in fact, they are less prone to accident than normal-sighted persons, possibly because they are more careful. A large number of engineering firms send the one-eyed workers back to their old jobs of grinding, turning, or drilling, wherein they are invariably found to be competent, be they young or middle-aged. Other firms refuse to put the men back on the old job, arguing that it is dangerous for them to do work in the tool-room or the engine-room. They therefore put the one-eyed workers on the more menial tasks, as in the store-room or the yard. A great number of firms require applicants to pass an eyesight test and do not employ one-eyed workers at all, so that the difficulties of the one-eyed workers increase when they lose their original employment. The inevitable result is that many of them drift into other occupations which involve a loss to their wage-earning capacity, to their self-respect, and to their social value to the community. In view of the number of one-eyed men discharged from the Services after the war, measures should undoubtedly be taken to improve their occupational prospects, and propaganda instituted to impress on public and private employers their negligible loss of efficiency in most vocations.

OCCURRENCE OF A FLAGELLATE IN THE SPUTUM OF A CASE OF BRONCHIECTASIS

BY

G. D. LEHMANN, M.R.C.S.

Major, I.M.S.

AND

J. T. PRENDIVILLE, M.B., B.Ch.

Major, I.M.S.

(From an Army Pathological Laboratory in India)

It is generally recognized that only one flagellate normally lives in the mouth of man and that it is correctly assigned to the genus *Trichomonas* Donne. It was discovered and originally named *Cercaria tenax* in 1773 by O. F. Muller (*Trichomonas tenax*). Gros (1849) described an amoeba parasitic in the human mouth and named it *Amoeba gingivalis*. This was amended to *Entamoeba gingivalis* by Brumpt (1910). Tibaldi (1920) described *Entamoeba macrohyalina* from the tonsil, which is probably the same. Knowles and Gupta (1924) published an account of a bodo (? *Bodo edax* Klebs), found to be a temporary resident in the human mouth, which was similar to that often occurring in water, urine, and faeces. From time to time, also, accounts have been published of protozoa found in the human lung. For example, in 1892, under the title of *Cercomonas*—formerly employed by medical writers as a general term for any flagellates of the human intestine—a flagellate was described by Streng in the sputum and in putrid expectorations in gangrene of the lung. Leyden and Jaffe (1867) observed infusoria in the putrid sputum of persons suffering from gangrene of the lung and putrid bronchitis. Parisot and

Simonin (1921) found what they identified as *Trichomonas hominis* (presumably *Trichomonas tenax*) in the pus from the cavity and in Dittrich's plugs in the sputum of a case of gangrene of the lung in life and directly after death.

Artault (1898) described under the term *Amoeba pulmonalis* a few amoeboid formations with a nucleus and vacuole in the contents of the lung cavern, distinguishable with difficulty from leucocytes. Brumpt (1910) refers to these as *Entamoeba pulmonalis*, and both he and Wenyon state that if they are amoebae, which is not at all clear, they are probably identical with *E. gingivalis*.

Previously it had not been our experience to find protozoa in respiratory secretions in such numbers as to excite attention. In the case described below the sputum of the patient swarmed with flagellates—a condition which may be of enough interest to merit recording. The details are as follows.

Summary of the Case

The patient, an Indian male aged 23, was admitted to hospital with a history of fever and rigors. Blood examinations showed the presence of *Plasmodium falciparum* and *P. vivax*. In spite of the usual antimalarial treatment his pyrexia continued and increased. He started to expectorate a considerable amount of foul-smelling sputum, which separated into three layers on standing. His respirations were laboured, and numerous crepitations were to be heard over the bases of both lungs. A lung abscess was diagnosed on Oct. 26, 1943—a fortnight after admission. Sulphonamide therapy was begun the following day, resulting in a rapid decline of his pyrexia; but it was without effect on his respiratory distress or the quantity and character of the sputum. The first specimen of sputum was received in the laboratory on Oct. 29, and when examined showed the presence of numerous flagellates and spirochaetes in addition to the customary fauna. In the case of subsequent specimens precautions were taken to avoid any risk of extraneous contamination. Examination of the sputum on four successive days revealed the persistence of these organisms. Gradually they became less numerous, and on the sixth day of the administration of sulphydryl they had entirely disappeared. The patient, now afebrile, worsened, and died on Nov. 12, 1943. Necropsy showed that both lungs were considerably fibrosed, with numerous irregularly shaped cavities filled with a foul-smelling gelatinous secretion. The general picture was that of long-standing bronchiectasis of the cylindrical variety. This was borne out by histological examination of the lung tissue.

Morphology of the Flagellate.—An attempt was made to ascertain the structure of the flagellate with a view to classification, but with only limited success. The flagellate, a pear-shaped organism measured 10–15 μ in length and 5–7 μ at its broadest point. At the narrowed anterior end it possessed two equal and anteriorly directed flagella about 10 μ in length. The flagellate showed great variation in shape, and in that respect appeared almost amoeboid in character. Frequently the posterior end became narrowed and elongated to form a caudal process. Progression, though mainly flagellar, appeared at times to be maintained by a combination of flagellar and amoeboid movements. If mucus was present there was tendency to burrow through it rather than to avoid it. Posteriorly vacuoles could be seen containing masses of debris, bacteria, and spirochaetes. Sometimes collections of debris, etc., could be seen adhering to the caudal process (cp. Jepps, 1923; Kofoed and Swezy, 1924: *Entamoeba gingivalis*). The nucleus was not evident in the unstained flagellate, but with Leishman's stain, and also with a combination of eosin and iodine, it was possible to make out the anteriorly situated nucleus. Iron-haematoxylin staining was attempted, but the first few preparations were not satisfactory, and unfortunately the flagellate died out before suitable preparations could be obtained. For the same reasons other means of investigation have not been carried out.

Discussion

There is little reason to doubt that the flagellates described above are nothing more than commensals living saprophytically on the decaying contents in the bronchiectatic cavity, and have apparently no pathological significance. It is of interest, however, to note that only the cases mentioned above have so far been recorded.

Two questions arise: first, what these protozoa were, and, secondly, how they obtained access to the lung.

Identity of the Protozoa.—From the examination of the dark-ground smears it was seen that they were either a *Trichomonas*—probably *tenax*—or *Dimastigamoeba gruberi*. Reference has previously been made to *Trichomonas tenax*. The following is a brief history of *Dimastigamoeba gruberi*. The family of

Dimastigamoeba includes the amoebae which are able in certain conditions to develop flagella and behave as flagellates. Schardinger (1899) isolated one of these from human faeces and named it *Amoeba gruberi*. From time to time similar amoebae developing flagella have been isolated and given various names by workers (Wasielewski and Hirschfeld (1910) *A. limax*, Alexeieff (1912), *A. punctata*, Martin and Lewin (1914) *Vahlkampffia soli*), and it is probable that they all belong to the same species. This species has since been shown to occur commonly in the soil and water and to be of the genus *Dimastigamoeba* founded by Blockman in 1894. This Rhizopoda illustrates very clearly a close relationship with the Mastigophora and could well be so classified. Wenyon (1926) describes the appearance of *Dimastigamoeba gruberi*. He states that on solid or liquid media the organism remains in the amoeboid state but that if a sudden change is made, if, for example a scraping from an agar plate is mixed with two or three drops of water—then in two or three hours an enormous number of flagellates appear, which after about 24 hours return to their amoeboid or cystic forms. When flagellation is complete the organism becomes pear-shaped, the more pointed end bearing the flagella. The nucleus normally approaches this end of the body, but may be at the thickened end. There is a slight cytostome and two blepharoplasts from which the flagella arise. A contractile vacuole is generally present in the thickened part of the body. The length varies from 10 to 30 μ . (See Diagrams 1 and 2)

Access of Protozoa to the Lung—Protozoa may reach the lung from (a) the buccal cavity, (b) the intestine (c) the blood stream.

(a) **From the Buccal Cavity**—It is conceivable that the flagellate might have originally been an inhabitant of the mouth and then passed into the lung, as presumably, in the case of *Trichomonas tenax* and *Entamoeba gingivalis* described above, but it is interesting to note that *Dimastigamoeba gruberi* has never been observed as a mouth commensal, nor were the flagellates found in the saliva when this did not contain the mucopurulent matter coughed up from the lungs. Minute animalcula could also be inhaled direct into the lung through the mouth, but a more feasible explanation may be obtained from a consideration of the mechanism of expectoration. Thus organisms taken into the mouth by food or water or inhalation may temporarily inhabit the buccal cavity perhaps in the encysted form. A patient in a weakened toxic condition brought about by chronic invalidism may not at times have the adequate propulsive force to ejaculate completely a large mass of viscid mucopurulent sputum from the trachea into the buccal cavity. In these circumstances part of the sputum may momentarily pass through the epiglottis and by nature of its elasticity and weight be retracted back into the trachea. To carry the speculation a stage further, the sputum may descend by force of gravity back into the bronchiectatic cavity, taking with it organisms from the pharynx.

DIAGRAM 2

SHAPES ASSUMED BY THE FLAGELLATE

A. FREE
B. IN CLUSTERS

They are perhaps the commonest of free living amoebae, and occur in soil and water everywhere.

In the present case it is probable that only amoeboid forms were present in the lung. After death the bronchiectatic cavities were searched for flagellates but these were not found. At the time it was thought that they had been destroyed by the course of sulphapyridine, but if these were *Dimastigamoeba gruberi*, another point must be considered—that is, that after death the protozoa were present only in the encysted or precystic form, and were not recognized as we had not then considered the possibility of a *Dimastigamoeba gruberi* infestation. Before death however, the amoebae in the mucopurulent material, on being coughed up from the cavities, became mixed with thin bronchial secretions and saliva. This change of medium, temperature, etc., probably caused them to become flagellates. At this time they were found in abundance in the sputum, but after this had stood for several hours they were no longer present. This would fit in with the change that normally takes place in the flagellate form of *Dimastigamoeba gruberi*, which always reverts back to the amoeboid or cystic state after some hours.

(b) **From the Intestine**—Unless this was by the blood stream (see below) or by the laryngopharynx, it was ruled out by the necropsy, which showed no direct connexion between the intestine and the lung.

(c) **By the Blood Stream**—This route cannot be ruled out entirely as Knowles, Acton, and Gupta (1929) refer to an *Enteromonas* and an *Octomitus* which had penetrated the wall of the gut and reached the blood stream. They also found *Trichomonas hominis* from films of the spleen and liver of the white rat. In none of these cases were any macroscopic injuries found in the gut wall, but it is important to note that these were all post mortem findings.

Summary

A flagellate was found in the sputum of a case of bronchiectasis in an Indian male aged 23.

This was shown to assume a great variety of shapes and to progress by a combination of amoeboid and flagellar movements.

It was pear shaped, 10-15 μ in length, with two equal flagella at the narrow end.

It is considered that this was either *Trichomonas tenax* or the flagellate stage of *Dimastigamoeba gruberi*, which had entered the

lungs by the mouth and had there found in the mucopurulent material of the bronchiectatic cavities an ideal medium, in which it had multiplied rapidly.

Various modes of entry are considered.

ABACTERIAL PYURIA

BY

DAVID O. PETERS, M.B., Ch.B., D.T.M.

Formerly Medical Officer, Nigeria

Abacterial pyuria is a designation applied to a group of cases which present a characteristic clinical picture and give a magical response to correct and adequate therapy, but the aetiology of which is still unknown. The recent article on the subject by Donovan (1945) has revived interest in a disease which, as he says, appears to be not sufficiently known to medical men as a whole. The two cases here described, which occurred in my practice a few years ago, may prove of interest.

Case I

Mrs. C., Irish, aged 33, 3-para, complained of frequent and painful micturition and terminal scalding but no haematuria. There was no fever or any constitutional disturbance. Duration, eight months. She had arrived in Nigeria twelve months previously to join her husband. Some eight weeks previously she had been admitted to a colonial hospital, where she stayed about one month, and had had a fairly thorough urological examination and treatment, but with only moderate relief. The medical officer who had treated her confirmed that she had had a full examination, including a microscopical and bacteriological investigation of the urine, which showed pus but no tubercle bacilli. A few bacilli belonging to the *B. proteus* group had been suspected. The treatment given was the one for cystitis, including the use of a sulphonamide preparation. *B. proteus* disappeared from the urine, but the general relief obtained was only mild. She was discharged from hospital, and proceeded to another station to join her husband. There, four weeks later, her symptoms recurred with tormenting severity, and I was called in.

Examination.—The patient was a highly intelligent woman, and she narrated her history with precision and clarity. Her condition was good: no abnormality was found in the general system. A catheter specimen of the urine was reported upon as follows: "Reaction, faintly alkaline; appearance, hazy. Albumin, trace; pus, ++; blood cells, +; vesical epithelial cells, ++; tubercle bacilli, negative; ova, terminal-spined, of *Schistosoma haematobium*, negative." Cystoscopy and other specialized forms of urological examination were not performed owing to lack of facilities.

Treatment given consisted of restriction of diet, abundant bland fluids orally, alternate three-days administration of acid and alkaline mixtures containing large doses of hyoscyamus, hot applications to the abdomen, hot enema, and hot hip-baths. Sulphapyridine is also used. The result was only slight relief. At my wife's end, I referred the patient back to the colonial hospital where she had formerly received treatment, and from there she was invalided home in order to receive further treatment.

Case II

Mrs. A., a Nigerian aged 22, 1-para, was seen in Feb., 1940, six months after Case I. Amenorrhoea had been present for 18 weeks. She complained of severe hypogastric and perineal pain, a frequent desire to micturate, and agonizing pain over the bladder during micturition. Haematuria occurred thrice, including an occasion in the hospital. The duration of the condition was 12 months. Dysuria was occasionally so severe that the patient would roll on the ground in agony.

Examination.—The patient's general condition was good. Pelvic investigation confirmed pregnancy and its duration, and negative a retroversion of the gravid uterus. Prolapse, tender caruncle, and vulvitis were absent. There was no Neisserian infection. Fever and rigors were not present. The laboratory report on the urine was as follows: Cloudy; reaction, alkaline; no albumin; pus, ++; blood cells, ++; epithelial cells, ++. No organism in film. Repeated examination for ova of the tropical parasitic trematode *Schistosoma haematobium* was negative. Cystoscopy was not done.

Treatment was given as in Case I, including the intramuscular administration, thrice weekly, of antihomaline, in spite of the negative laboratory report of schistosome infection. There was no relief after three weeks' intensive treatment.

At this juncture an issue of the *B.M.J.* (Feb. 3, 1940) arrived by ocean mail; and on glancing through it I was struck by the curious title of an article—"Abacterial Pyuria," by Mr. Thomas Moore. I read the article through at once, and found that the symptoms and signs shown by my present and previous cases were identical with those of the case reported in Moore's instructive paper. That day I administered N.A.B. 0.3 g. intravenously. The result was almost magical. The following day there was a remission of all the symptoms. It seemed too good to be true, but it was true. I gave altogether four N.A.B. injections intravenously—twice weekly for two weeks. The first dose was 0.3 g., but other doses were 0.45 g. each. A few months later, at full term, the woman was normally delivered of a healthy male child.

I saw the patient again, early in 1945, when she reported complete freedom from the complaint since her treatment.

Commentary

The two cases here reported occurred in Nigeria; both were women—one a European, the other an African. Both were parous, one being actually pregnant when first seen and tracing the onset of her symptoms to some time before the pregnancy. The symptoms in both women were severe, but it would appear as if the severity was greater in the pregnant one. This might have been due to the heavy, rising, antelexed uterus pressing somewhat on the inflamed bladder.

Sex Incidence.—The series of cases under discussion would appear to support Moore's statement that the disease is more common in men. His case, reported in 1940, occurred in 1939 in an unmarried woman. The two cases described above occurred in women both of whom were married and parous. Donovan's five cases reported recently were in men, and he was constrained to remark, "I have not met with the condition in the female."

Age Incidence.—In Moore's case the woman was 52 years old when first seen. The ages of my two patients were 33 and 22 years. The ages of Donovan's five cases ranged between 35 and 52 years. The series of cases under discussion is obviously too small to work upon, but it would seem to show that the condition is found between the ages of 22 and 52 years, and that persons in the fourth, fifth, and sixth decades of life are more prone to attack. In the present combined series three cases occurred in the fourth decade (33, 35, and 40), three occurred in the sixth decade (51, 52, and 52), and two in the fifth decade (49 and 50).

It is significant that no case below the age of 20 years has been recorded. The greatest incidence in this series occurred during that period of life when the urethro-vesical area is perhaps more exposed to various forms of physical and organismal traumata, and when there is often some amount of retention of urine in the bladder—either voluntary or pathological—leading to congestion of the bladder mucosa and predisposing to microbic attack.

Facilities for cystoscopy, excretion urography, ureteric catheterization, and guinea-pig inoculation may not be available, but a thorough urine examination should always be done. The reaction of the urine may be neutral, alkaline, or acid. It should be remembered that "an acid urine implies infection with the *B. coli*, *B. tuberculosis*, or the gonococcus" (Beaumont, 1937). In the two cases under review the urine was cloudy in appearance and alkaline in reaction. The two-glass test is often helpful. It was carried out in Case II only, and both glasses were equally cloudy.

One important point is to determine the presence or absence of tubercle bacilli. The organisms must be carefully looked for in the urine. This is done by centrifuging and staining a 24-hours specimen of the urine. In a case of urinary tuberculosis the organisms are nearly always present, but repeated

examination and the use of the guinea pig may at times be necessary. Pus blood cells and vesical epithelial cells are usually present in the urine. In the Tropics schistosome eggs must be sought for in the urine for blood and pus may accompany painful micturition in bilharzial disease.

The prognosis in abacterial pyuria appears to be quite good. No mortality has been reported. In one of my two cases the patient was still free from symptoms five years after treatment.

The aetiology of the condition is unknown and is merely speculative. Moore and Donovan favour the virus theory. Lydon (1945) however stated that he had had the opportunity of having several slides stained and examined by experts in virus work but with negative results.

In regard to treatment it is noteworthy that intense sulphonamide therapy brought no relief in either case nor in Donovan's cases. Anthiomaline which was used in Case II had no influence on the disease.

The introduction of prontosil caused a startling fall in the mortality from haemolytic streptococcal infections. This gratifying result led to the trial of the preparation in affections due to organisms belonging to the same group—the gonococcus meningococcus, etc. The result was also satisfactory. Further research work yielded compounds (the sulphonamides) derivatives of prontosil, possessing a greater potency and efficacy. These compounds had a curative effect on the same types of micro-organisms. In other words a certain preparation destroyed or restrained the activity of a microbe which belonged to a group of organisms having certain characteristics in common. It was reasoned that as that preparation destroyed or inactivated the one organism it was likely to do so with the others of the same group. And to a great extent that was what happened. Now, N.A.B. has a high therapeutic index in syphilis, yaws, rat bite fever, relapsing fever (house borne and tick-borne), Vincent's angina, etc. These diseases are caused by microbes of the spirochaete group. N.A.B. causes a similar rapid disappearance of symptoms and signs in abacterial pyuria.

Spirochaetes as a rule are rapidly destroyed by the administration of arsenic and it is practically true that, in the present state of our knowledge, there is no other group of micro-organisms so readily and rapidly destroyed or inactivated by N.A.B. or any other similar arsenical preparation as the spirochaetal group.

The certainty of cure, by N.A.B. of abacterial pyuria and particularly the rapidity and completeness of the cure—just as obtains in those affections caused by spirochaetes—would lead one to suppose that an organism particularly susceptible to an arsenic compound was concerned in its causation, and that the organism probably possessed similar biological characteristics to those of the group concerned in the aetiology of syphilis, yaws, etc. It may not be amiss therefore to postulate that the cause of abacterial pyuria is an organism pertaining to the spirochaete group, which organism has so far eluded capture owing probably to a slight morphological peculiarity. The result of a Wassermann test in this disease would be of particular interest.

The mode of infection of the causative organism whatever it may be, is also speculative. Direct contact is possible. The husbands of the two women whose cases are here reported declared that they had not at any time suffered like their wives and they actually appeared to be in good health. I examined the husband of Case II for evidence of specific or Neisserian infection with negative result, but the man admitted a previous gonococcal infection which had received proper treatment. These facts prove very little for a detailed urine examination or a serological test of the men had not been made. It was possible that an organism in an attenuated form had been present in the men and had under favourable conditions in the women incidentally assumed a pathogenic character.

The causative organism of abacterial pyuria may be a virus. This is an open question. But it is significant that there is no virus disease which has yet been shown to benefit by N.A.B. or any other known preparation of arsenic. Paradenitis, varicella, vaccinia, varicella morbilli, etc. are virus diseases. They are not influenced by N.A.B. which has a magical effect in abacterial pyuria but the sulphonamides which do not benefit abacterial pyuria, often exert a favourable influence in virus infections.

One other point. There is a clinical entity known as Hunner's ulcer. It is also sometimes called submucous ulcer of the bladder or referred to as intramural cystitis. The ulcer if ulcer it may be called is situated mainly in the submucous and muscular coat and there is often little to see on cystoscopy except a bleeding pin point spot (Bailey and Love 1938). The clinical feature of this disease and the pathological changes in the bladder are practically identical with those found in abacterial pyuria. In either the aetiology is not known. The treatment of Hunner's ulcer is difficult and may require surgical intervention. I do not know if N.A.B. or any substance closely resembling it has ever been tried. The result of a Kohn or Wassermann test in both conditions should prove of interest.

Are both conditions—abacterial pyuria and Hunner's ulcer—one and the same disease?

TWO CASES OF AMOEBIC GRANULOMA

BY

GWYN HOWELLS, M.B.

Capt. R.A.M.C.

Amoebic dysentery with frequent relapses is one of the commonest causes of repatriation on medical grounds of Service personnel from the Eastern theatre of war. Amoeboma is an infrequent complication of amoebiasis that may be mistaken for neoplasm. There seems to be no reason why such cases should not be met with in Britain in the post-war years.

Before this war case reports of amoebic granulomata appear to have been comparatively few in the English language. Zachary Cope (1920) refers to cases in which amoebiasis was mistaken for carcinoma. In 1931 Gunn and Howard, in reporting three cases of amoebic granuloma were able to find only six previous references in the literature. They pointed out that the signs and symptoms may be identical with those of neoplasm. The pre-operative diagnoses of their cases were: (1) carcinoma of the transverse colon in a man aged 37; (2) carcinoma of the caecum in a man also aged 37; and (3) carcinoma of the colon in a man aged 41. Two of these patients died as a direct result of operation. Two of the cases were due to war service overseas one of these occurring as many as twelve years after return to the homeland. Yeomans (1936) describes a case of amoeboma occurring in the rectum and another case simulating carcinoma of the colon. He emphasizes that radical treatment by surgery is almost invariably fatal without anti-amoebic treatment. Naunton Morgan (1944) describes a case of amoeboma disappearing after a month's treatment.

Case 1

The patient an Indian sepoy aged 27, was admitted to the V.D. ward of an Indian military hospital as a case of syphilitic condyloma of the anus. He gave a history of having a penile sore seven months previously; this had been diagnosed as syphilis. Penicillin treatment had been started but, after eight or nine injections of neosphenamerine and bismuth treatment had been allowed to lapse. He had had the present symptoms of a "growth" in the anal region for two months before reporting it. He had also had several previous attacks of malaria and dysentery, but none within the last two years.

On examination there was a warty lumpy mass extending for about an inch (2.5 cm.) around the anal margin. The surface was iridescent reddish in colour, and exuded a thin discharge. There was no thickening of surrounding tissue and the anal margin itself was not involved. General examination revealed only the scar of the old penile sore and some degree of anaemia. The Wassermann reaction was positive on three occasions. Examination of the discharge for *Treponema pallidum* was positive. Antisyphilitic treatment was begun.

After a complete first course of treatment the condition was slowly worsening. The surface of the mass was breaking down and the whole was gradually extending both outwards and inwards so as to involve the anal margin. Just after the beginning of his second course of treatment the patient was sent to see a surgeon who reported that there was a large infiltrating mass involving the anal

canal and that the condition seemed likely to be carcinoma of the anus. Biopsy was done immediately and the pathologist reported an inflammatory condition with no evidence of neoplasm. Swabs taken from the surface at this time showed a heavy mixed bacterial infection of the mass.

The patient was seen by a physician, who suggested the possibility of amoebic granuloma. Further examinations of the discharge and stools were made, with negative results. Despite this, treatment was started with 1-gr. (65 mg.) emetine hydrochloride injections daily. After the fifth injection the mass began to retrogress rapidly, and by the tenth day it was dry and half its original size. After 10 gr. (0.65 g.) had been given the emetine was discontinued. In three weeks healing was almost complete. Re-examination a month later showed no evidence of the disease.

Case 2

This patient, a merchant seaman aged 36, complained of an anal tumour of a month's duration. The tumour had first been noticed as a small protuberance from the anus which the patient had thought to be a haemorrhoid. His attempts to replace it had resulted in considerable trauma and bleeding. After this, he stated, the tumour had remained stationary in size for eight or nine days; since then it had grown rapidly. He gave a history of many attacks of dysentery, the most recent being three months previously. He had no symptoms of dysentery at present, but was liable to relapses at any time.

On examination there was a raised mass about an inch and a half by one inch (40 mm. by 25 mm.) involving the posterior anal margin and spreading backwards. The mass was hard, grey, not tender, and had an ulcer crater exuding a dark thin pus. Examination of the pus revealed numbers of active amoebae. Several examinations of stool showed no amoebae, but cysts were found on each occasion.

Treatment was carried out as in Case 1, and results were equally successful and rapid.

Discussion

The situation of the tumour in the two cases is unusual, the most often recorded region for amoeboma being the colon. It is interesting to note the pre-existence of local tissue damage in each case—in Case 1 a syphilitic lesion, and in Case 2 a probable trauma. The response to treatment was in both cases excellent, but it is not always so. Naunton Morgan states that the results of anti-amoebic treatment depend on the duration of the tumour and the resultant degree of fibrosis. Reed and Geiger (1943) state that "operations involving the gastrointestinal tract, when amoebic lesions are present untreated, are likely to prove fatal." They also state that carcinoma is among the sequelae.

The difficulty of diagnosis if cases should occur in this country is obvious. The history of overseas service or amoebic dysentery is essential to the diagnosis, for unless this is obtained it is improbable that investigations for signs of amoebiasis would be made. Naunton Morgan points out a pitfall in the diagnosis: carcinoma and amoeboma may coexist.

Summary

Two cases of amoebic granuloma—an infrequent complication of amoebiasis—are described. Both cases responded well to anti-amoebic treatment. The possibilities of misdiagnosis as neoplasm are emphasized. Amoeboma may occur years after the last recognized attack of dysentery.

My thanks are due to Lieut.-Col. R. L. Haviland-Minchin, I.M.S., for diagnosis of the first case and for much helpful information.

CRUSH SYNDROME AND PLASMA JAUNDICE IN PREGNANCY

R. W. DANZIGER, M.B., B.Chir., D.R.C.O.G.

Assistant Medical Officer, St. Mary Islington Hospital (L.C.C.)

Both crush syndrome and serum jaundice are conditions which only recently have they come into the limelight. They occurred together in the case reported below and failed to interfere with an early pregnancy.

Case History

The patient, a 21-year-old primigravida in the third month of pregnancy, was admitted to this hospital on New Year's Day, 1945, after being buried under masonry for 12 hours when her home was blasted by a rocket. On admission she was cold and shocked, with a blood pressure of 80/50 mm. Hg and a rapid and thin pulse (130). Bruises and abrasions were found all over the body and limbs. In addition the right ear and left labium majus were oedematous and tender. There was no bony injury anywhere, but the patient was unable to feel or to move her left foot and toes (which had been caught under a beam), and both the plantar and dorsal aspects showed dry indurated areas. These had a leathery feel, and the skin was adherent to the underlying tissues. A little later an attempt was made to mobilize the skin in these areas so as to increase its blood supply.

Immediately after admission to a warm bed she was given 1/4 gr. (16 mg.) of morphine and an intravenous drip of plasma was set up. By the evening the pulse rate was 148, temperature 99°, and the general condition unchanged. No urine had been passed, and at 3 a.m. on the following morning 6 oz. (170 c.cm.) of deeply blood-stained urine was obtained on catheterization. Restlessness during the night necessitated a further injection of 1/4 gr. of morphine.

On Jan. 2 her general condition seemed slightly improved after the administration of 3 pints (1.7 litres) of reconstituted plasma. The temperature was normal and the pulse rate 120, with better volume. Fluids were well tolerated, though nausea and occasional vomiting persisted. The left arm and leg were swollen and aching; they were held immobile, but passive movements were painless. The right ear was badly swollen and blistered, with a clear discharge. Various other complaints were due to bruises of the head and trunk. The fluid output, however, was ominously unsatisfactory; on this day it amounted to 5 oz. (142 c.cm.) only. Rectal and intravenous drips were set up, glucose solution being given by the former and 3.8% sodium citrate by the latter. This was later changed to 4.2% sodium sulphate in an effort to promote diuresis. Biochemical examination of the blood gave the following results: Blood urea, 62 mg. per 100 c.cm.; alkali reserve, 64 vols. CO₂; blood phosphorus, 7.04 mg. per 100 c.cm.; and plasma chlorides (as NaCl), 490 mg. per 100 c.cm.

The patient was distinctly worse on Jan. 3. Colour and pulse were less satisfactory, and there was much sickness. Very little urine (3 oz.: 85 c.cm.) was passed, and what was passed was deeply blood-stained. She was becoming waterlogged, especially the left side of face and body, also the limbs on that side. She took fluids by mouth, but complained of nausea and general listlessness. The swollen parts were not painful. In an effort to increase urinary output it was decided to continue the intravenous drip, but to substitute hypertonic glucose-saline for the sodium sulphate solution.

By Jan. 4 the drip had slowed down considerably and was discontinued, the patient now having had altogether 11 pints (6.25 litres) of fluid by that route, of which only a negligible amount had been excreted. Nevertheless she complained of a dry mouth and was taking fluids fairly liberally. On this day she passed no urine at all, and in the evening 4 oz. (114 c.cm.) of urine was found in the bladder on catheterization. The left side of the face, the left leg and arm, also the vulva, were now grossly oedematous. The blood urea rose to 100 mg., but the patient remained mentally alert.

During the next three days the patient's condition remained unchanged. There was no more sickness, and her colour, pulse, and mentality were remarkably good. The entire left side of her body, which had evidently been crushed more than the right, remained very swollen, and the limbs were put on back splints to prevent wrist- and foot-drop. Vague abdominal discomfort was felt and there was some difficulty in swallowing. She took fluids quite well by mouth, so no further intravenous administration was resorted to. On Jan. 5 she passed 6 oz. (170 c.cm.) of urine, on the 6th a total of 8 oz. (227 c.cm.), and on the 7th 14 oz. (397 c.cm.). Mr. Clifford Morson, the urological consultant, for this reason advised against renal decapsulation, which had been considered.

From Jan. 8 there was definite improvement in the general condition, coinciding with an increased fluid output. Oedema was still pronounced, being most troublesome in the vulval region. The left arm could now be moved a little, and sensation was not affected, while the left leg was immobile and anaesthetic from the knee downwards.

U.F.A.W. (the Universities Federation for Animal Welfare) has issued a new prospectus from 284, Regent's Park Road, Finchley, N.3. In spite of the bombing of its office and the death of the secretary it appears to have made considerable progress during the war, and has attained to a recognized position in the scientific world. The new president is Prof. Edward Hindle, F.R.S., and the vice-presidents include seven Fellows of the Royal Society and three Members of Parliament for universities.

Progress was steady during the next few weeks. The oedema gradually subsided, and as much as 8 pints (4.54 litres) of urine was excreted in a day, the kidneys evidently recovering. The patient was sick at times, but this was thought to be due to the pregnancy, which was progressing satisfactorily. Electrical treatment was given to the left leg, and throughout February this was the patient's only remaining disability. On Feb. 11 she was seen by Mr. R. Blunden, who reported: "Left leg paralysed below knee, both anterior and posterior muscles. Anaesthesia distal half of foot much less than on admission. Skin in good condition. Quadriceps functioning well. I recommend toe-raising spring and double irons to below knee, with chuck to prevent plantar flexion at ankle to more than 90°, but to allow dorsiflexion."

On March 31—i.e., exactly three months after her admission—the patient was noticed to be jaundiced. She had not been feeling so well for two days; there was nausea, but no other symptoms or signs. Bile pigments were present in the urine for a short time, and the icterus began to fade within a few days. There had been no instance of jaundice among the patient's relatives and friends who had come to visit her, and this must undoubtedly be considered a case of plasma jaundice. Biochemical examination of the blood at this stage led to the following results, which represent a small degree of liver damage:

Colour index	1.11
Red blood corpuscles	3,950,000 per c.mm.
Haemoglobin	85%
White blood corpuscles	11,400 per c.mm.
Polymorph neutrophils	60%
Lymphocytes	35%
Large mononuclears	3%
Platelets	Normal
Sedimentation rate, 1 hour	34 mm. (Wintrobe)
Cell volume	40%
Van den Bergh reaction:	
Direct	Weakly positive
Indirect	2 mg. bilirubin per 100 c.cm. (4 V.D.B. units)
Takata-Ara reaction	Weakly positive
Formol-gel test	Negative
Alkaline serum phosphatase	16 units
Blood urea	26 mg. per 100 c.cm.
Serum proteins, total	6.2 g. %
Albumin	4.0 g. %
Globulin	2.2 g. %
A/G ratio	1.8/1

When the patient was discharged on April 27 her general condition was excellent. The urine was normal, B.P. 125/75 mm. Hg, and the height of the uterus indicated a 6-months pregnancy. Some oedema of the left labium majus had persisted, the left arm had completely recovered, but the left leg remained a little swollen, paralysed below the knee, and anaesthetic in the foot. During the remainder of her pregnancy the patient attended the antenatal clinic periodically, but there was never any abnormality. She went into labour spontaneously on July 16 and had a normal delivery of a healthy male infant weighing 6 lb. 6 oz. (2.9 kg.) on the following day. During the puerperium, which was uneventful, she was again seen by Mr. Blunden, who found: "Quadriceps working. No muscles acting below knee, and there is anaesthesia of foot and front of leg, 1½ in. (3.2 cm.) wasting of thigh, and 1½ in. (3.8 cm.) wasting 4½ in. (10.5 cm.) below joint line. Response to galvanism present; no response to faradism."

Discussion

There has been considerable interest in the crush syndrome since Bywaters drew attention to it in 1941. This was the first account in this country, though Bywaters (1942) himself pointed out that the condition had previously been described by German authors. It occurs exclusively in persons who have been buried for several hours, with special pressure on a limb. The majority of the reported cases ended fatally, necropsy revealing more or less extensive local necrosis of muscle and degeneration of renal tubules. So long as this damage is of a minor degree—as was probable in the case described—recovery seems to be possible. The urinary output is the best indication of renal competence. In those who die, vomiting becomes persistent; the blood urea rises; urine is scanty or absent; and they eventually pass into uraemia.

The oedema of the damaged limb is tense, rarely pitting, and usually progressive. It is, as a rule, accompanied by paralysis, anaesthesia, and impaired circulation, so that in some of Bywaters's cases the affected part was incised to relieve the tension. On the assumption that autolytic products liberated in the dead or dying tissues are responsible for severe constitutional disturbances, amputation has been performed; but to have any chance of success this course would have to be adopted very early, and at that time shock usually prevents major surgery.

In an endeavour to cause a diuresis, intravenous fluid was given, and continued, with some trepidation, even when the output became practically negligible and the patient waterlogged. Plasma was used at first, and was later replaced by alkaline solutions and saline. The need of the body for alkali and chlorides, indicated by the acidity and low chloride content of the urine, has been noticed by other workers (Blackburn and Kay, 1941; Bywaters and Beall, 1941).

Jaundice, occurring about 90 days after a plasma transfusion, is now a familiar event. There was no other instance of jaundice either in the ward or among the patient's friends and relations, so that the aetiology cannot be doubted in this case. Moreover, the illness was of a lighter and more transient nature than is usual with infective hepatitis.

Finally, it is of interest to note that neither the crush syndrome nor the plasma jaundice had any effect on the pregnancy, which continued normally. The patient ultimately had a normal confinement, and the baby seems to be none the worse for his antenatal experience. The patient herself is now left with a paralysed and anaesthetic foot, and, in view of the slow progress (if any) over the past few months, one wonders whether it will ever recover.

My thanks are due to those of the consultants, and of my colleagues on the resident staff, who gave me the benefit of their advice in the treatment of this patient. I should also like to record my indebtedness to the laboratory technician—Mr. P. Chappell—who carried out the various investigations with keenness and enthusiasm; to the nursing staff, without whose devotion this patient would not have recovered; and, above all, to the patient herself for her endurance, co-operation, and never-failing confidence, although so desperately ill.

BACTERIOLOGY OF SEPTIC FINGERS

BY

B. P. Le QUESNE, B.M., B.Ch.

(From the Bland-Sutton Institute of Pathology, Middlesex Hospital)

The following is an account of an investigation planned to discover the rate of secondary infection in infections of the finger and hand, incised and treated in a casualty surgical department; and, at the same time, to assess the incidence of the various pathogens as primary infecting agents.

Methods

The cases were in no way selected, and consisted of a consecutive series of septic lesions of the hand requiring incision, and not severe enough to warrant admission to the wards. The majority of the cases were paronychia, pulp infections, and web-space infections, though there were a certain number of simple subcuticular abscesses, etc., in various parts of the hand and fingers. The fingers were operated on in the casualty department; the surgeon never wore a mask, and used ungloved hands. The dressings were changed either in the main casualty room or in a small side room by a student or nurse, using the fingers: a "no-touch" technique was not employed. Masks were not used by those doing the dressings. Inquiries showed that usually, but not invariably, the nurses "scrubbed-up" before changing a dressing, but at times they passed from case to case without washing their hands. It was not uncommon for patients themselves to remove their dressings.

No attempt was made to adopt a standard treatment for the cases under observation, the surgeon in charge altering the treatment as and when required. Eusol-and-paraffin was the common dressing; sulphathiazole paste, proflavine, magnesium sulphate, were all used frequently. Many of the patients received physiotherapy, which involved quite prolonged exposure of the wound without a dressing; after this treatment the dressing was renewed.

A swab was taken from the lesion at the time of incision, and further swabs, so far as was possible, at two-day intervals until the finger was healed. Cases were considered to be healed when it was no longer necessary for them to wear a dressing and continue to attend hospital. The swabs were inoculated

on to two 3% horse-blood agar plates and incubated for 18 hours at 37° C.—one aerobically and the other in a CO₂ jar, as it has been shown (Rose, 1942) that CO₂ in the atmosphere increases the frequency with which small numbers of β -haemolytic streptococci may be isolated when growing in company with a heavy growth of *Staph. aureus*, etc. From over 600 swabs β -haemolytic streptococci were twice isolated from the CO₂ culture when they could not be identified on the normal aerobic plate. All staphylococci isolated were tested for the production of coagulase: the "slide-test" technique (Cadness-Graves *et al.*, 1943) was used as a routine, but if this was negative the organism was subcultured in broth and a tube test was carried out; if this test was positive such organisms were recorded as being coagulase-positive. No strains of *Staph. aureus* which were coagulase-negative were encountered, and vice versa, so that in what follows *Staph. aureus* may be taken as synonymous with coagulase-positive staphylococci and *Staph. albus* with coagulase-negative ones. All suspicious streptococci were tested for the production of soluble haemolysin, and if this was positive their Lancefield group was determined by Fuller's formamide method.

Owing to the extreme variation in the patients' times of attendance, and other uncontrollable factors, it was not possible to adhere strictly to the routine of swabbing each finger on alternate days. However, it was decided not to accept any case in which more than five days elapsed between two swab-bings, although we accepted one case which took 46 days to heal and in which no swab was obtained between the 16th and 23rd days. Similarly, cases were rejected in which more than five days elapsed between the last swab and healing. In two cases an adequate incision had been made before the patients attended hospital, but they are included, as in both cases a pure culture was obtained from the first swab.

Results

In order to obtain 100 acceptable cases swabs had to be taken from 155 patients; the initial swab from the entire series showed *Staph. aureus*, either alone or accompanied by some other organism, to be present in 89.02% of cases, and β -haemolytic streptococci similarly in 7.7%. In 13.5% more than one organism was isolated from the initial swab. It is of interest that in three of the cases from which β -haemolytic streptococci were isolated from the finger lesions the patients had coincident sore throats from which β -haemolytic streptococci of the same Lancefield group were obtained, and in the one case investigated the two organisms were of the same Griffith type. From the initial swab of the 100 fully investigated cases *Staph. aureus* was isolated from 93% and β -haemolytic streptococci from 5%.

Altogether 499 swabs were examined from the hundred completely investigated cases; the greatest number from one case was 32—from a pulp-space infection which took 95 days to heal. Of these hundred cases 18 became secondarily infected before healing, four of them with two organisms. Thus on 22 occasions a secondarily infected organism was isolated, and their distribution is shown in the accompanying Table. Of these

Table showing Incidence of Secondary Infecting Organisms

Organism	A	B
β -haemolytic strep.	4	3
<i>Staph. aureus</i>	6	3
<i>Staph. albus</i>	5	2
Non-haemolytic strep.	1	0
Epithelioids	3	0
" "	1	0
"-yaneus	1	0
<i>M. catarrhalis</i>	1	0
Total	22	8

A, Total. B, Established infections. All four strains of haemolytic streptococcus isolated belonged to Group A.

22 organisms 14 were recovered on one occasion only, and in none of the four doubly infected cases were both organisms isolated more than once. This leaves 8 cases (8%) which developed established secondary infection, the responsible organisms being shown in the table. Six out of the seven cases in which *Staph. aureus* was not present initially

developed infection with this organism, though in three it was isolated on only one occasion.

The average time between incision and healing in cases not developing secondary infection was 11.12 days, and in those developing such infection 20.88 days. Owing to the large variation between cases and the comparatively small number studied these figures cannot be considered significant.

Discussion

Beyond stating that infections of the hand are commonly due to *Staph. aureus*, with an occasional haemolytic streptococcus infection, the textbooks on surgery of the hand do not go into the bacteriology of such lesions. Florey and Williams (1944) and Williams and Miles (1945), who investigated septic fingers and hands from different aspects, give figures for the incidence of streptococcal and staphylococcal infections. But in many of the cases of Florey and Williams certainly, and in some of those of Williams and Miles apparently, the patients were admitted to the wards, which suggests that the lesions were more serious than those investigated here. In the present series all cases needing incision were investigated, including many minor subcuticular lesions, etc. Florey and Williams confined their attention to definitive conditions such as paronychia, web-space infection, septic lacerations, etc., and Williams and Miles did the same, though adding a final category of miscellaneous septic conditions, many of which apparently did not need incision. Thus for two reasons comparison between the infecting organisms in the three series is of little value, and apart from these two papers recent literature does not contain any work on this subject.

With regard to the incidence of secondary infection, it is doubtful whether the figure of 14% represents the true state of affairs. At the time this work was being carried out it was not possible accurately to distinguish one strain of *Staph. aureus* from another, so that in those lesions initially containing this organism it was impossible to determine whether or not they later developed superadded infection with another strain. But in the 7 cases in which *Staph. aureus* was not at first present it was later isolated from 6—a fact which suggests that many of the other 93 cases in which it was present must have developed a secondary infection with a different strain of *Staph. aureus*, and that the true level of secondary infection is considerably higher than 14%.

Florey and Williams record a secondary infection rate of 19% in their series of 212 cases of infection of the fingers, hand, and arm; but again any comparison between this and the rate discovered here is invalidated, owing to the different nature of the lesions and the fact that many of Florey and Williams's cases were treated as in-patients. There does not appear to be any published work dealing with secondary infection in casualty departments. It is obvious that the figure of 14% cannot be interpreted as representing the level of secondary infection in all wounds treated in such departments: the fingers under consideration, with their daily dressings and gaping incisions, offer greater chances of secondary infection than clean incised and sutured wounds healing by first intention which form a large percentage of the cases treated in these departments.

A secondary infection rate of 14% is much lower than the shown by Miles *et al.* (1940) to exist in open wounds treated in the wards, where it was in the neighbourhood of 50% nevertheless, if it can be shown that 14%—or, as is likely a figure somewhat in excess of this—represents the average incidence of secondary infection in septic fingers, it is obviously important that the subject should be investigated further, with a view to determining to what extent such infection adversely affects the progress of the disease. In addition, it is apparent that in the casualty department in question, at any rate, the surgical and dressing techniques might be considerably improved in the light of recent knowledge (M.R.C. War Memoranda Nos. 6 and 11). There is now a large volume of evidence to show that the secondary infection rate in wounds can be materially reduced by means of a rigid aseptic technique and the intelligent use of wound antiseptics. As Paterson Ross (1941) says, "The same considerations apply to dressing wounds at first-aid posts and in the out-patient departments of hospitals—really a much bigger problem and harder to deal with than

ward dressings—and also to dressing wounds which are already grossly contaminated.”

My thanks are due to Prof. J. McIntosh for his help in putting this article together; to Dr. C. J. C. Britton for his advice and encouragement; and to the staff of the casualty department for their willing co-operation.

Medical Memoranda

Repair of Femoral Artery after a Bullet Wound

The following is an interesting case thought to be worthy of publication.

Pte. A. of an Airborne Division was wounded on April 7, 1945, by a bullet which passed through his left thigh from back to front. He was admitted to a casualty clearing station in a Schloss near the Rhine, after a long journey and some delay caused by the very rapid advance in which his unit had taken part.

On admission his left thigh was nearly twice the size of the other. His foot was stone cold, and he said it felt as if it was frozen. No pulse was palpable at the knee or foot. Behind was a small entry hole in the mid-thigh, slightly medially, while in front was an exit hole about 14 in. (3.8 cm.) across, surrounded by bruised skin. The bone was not broken.

Under general anaesthesia, administered by Capt. L. W. Spratt, R.A.M.C., an operation was performed about 47 hours after the patient had been wounded. The limb was thoroughly cleansed and the large exit wound was excised, enlarged, and explored. The femoral vein was found torn in half and surrounded by huge blood-clots. It was ligated. The femoral artery was torn round three-fifths of its circumference, and also contained a clot. Since this wound made access to the femoral canal rather difficult, a new incision was made 3½ in. (9 cm.) long in the line of Hunter's canal. The femoral artery was clamped above and below its site of injury, and the clot removed. End-to-end anastomosis was performed, using an 00 suture of catgut. The suture was small continuous-suturing, evertng the endothelium. A portion of the long saphenous

FIG. 1

FIG. 2

vein was excised and opened up longitudinally. This was used as a cuff round the femoral suture line, and sutured above and below it. The clamps were removed. Pulsation restarted, and could be felt in the femoral artery distal to the suture line. Next the adventitia was stripped from the vessel for a distance of 14 in. (3.8 cm.) above and below the suture line to obviate local spasm. The femoral artery was then buried in the sartorius muscle after a bed had been made there for it. The wounds were dusted with penicillin-sulphanilamide powder, and dressed with tulle gras, gauze wool, and bandages. By the time the bandages were in place the foot was warm and pulsation in the dorsalis pedis artery could be faintly felt. No heparin was given, as none was available.

The next day sensation and movements of the foot and toes were normal. Seven days later, when the patient was evacuated to a base hospital, the wound was healthy, sensation was normal in the foot, and he could bend his knee and waggle his foot. A follow-up card was sent with him. On Aug. 15 I received the follow-up card with the following information upon it, for which I am very grateful.

"Park Preswet Vascular Unit, Basingstoke, Hants.—The above patient arrived here on July 3, 1945, and we were impressed by his good condition. Mr. B. C. Maybury considered the result to be far better than a primary ligature. On April 17 it had been noted that distal pulses were absent. The artery had probably thrombosed, but on admission here had either recanalized or collateral circulation had developed. B.P.: R. leg. 155/85; L. leg. 130/78. Pulses were present. Power of leg good. No ischaemia of muscles. No intermittent claudication."—(Signed) D. O. Williams, Asst. Surgeon.

The patient is now undergoing rehabilitation at a convalescent depot.

J. A. VERE NICOLL, F.R.C.S.D.,
 Major, R.A.M.C.; late Surgeon to a Field Surgical Unit.

Reviews

EXAMINATION OF THE BONE-MARROW

Die Untersuchung des Knochenmarkes. Die Hämatologie im Lichte der Sternalpunktion. By Dr. Med. Stefan J. Leitner. (Pp. 355; illustrated. Swiss francs.) Basle: Barm Schwaab and Co., Verlag Klotzberg 27.

Although a relatively simple method of trephining the sternum was introduced by Seyfarth in 1925, it was the invention of the sternal-puncture needle by Arinkin in 1929 which made the examination of the bone-marrow in life generally practicable. So rapidly has the technique developed that this latest monograph comprises nearly 400 pages, of which 50 are devoted to the list of references to the literature. The book is based on a personal experience of 2,000 sternal punctures in more than 700 patients, and is well produced. There are six small colour plates, and the text is illustrated by photomicrographs. An untouched photograph may be true to life, but as an illustration it cannot compete with an artist's drawing or painting. The author begins by describing the normal appearance and distribution of the marrow cells, and he emphasizes the value of studying the occurrence of mitosis. The disturbances of erythropoiesis, leucopoiesis, and thrombopoiesis in various blood disorders and general diseases are then described in detail. A number of technical applications are considered, such as the administration of infusions and transfusions by way of the marrow, and the value of sternal puncture in the diagnosis of infectious disease. It appears that sternal puncture may be of assistance in the diagnosis of tropical diseases, including typhus and typhoid, but it contributes little to the diagnosis of sepsis or tuberculosis. Marrow withdrawn by sternal puncture has also been used for microchemical investigations and tissue cultures. Dr. Leitner has undoubtedly succeeded in producing a competent and comprehensive account of the examination of the bone-marrow in life. The obvious applications of sternal puncture are in the diagnosis of the atypical megalocytic anaemias and the leucopenic or aleukaemic leukaemias. It is also of value in the differential diagnosis of the haemorrhagic diseases, and the selection of patients likely to benefit from splenectomy. But, above all, sternal puncture has familiarized the present generation with the morbid histology of the blood and has taught us to regard a blood disorder as a biological process and not a static picture.

HEALTH INSTRUCTION

Health Instruction Yearbook, 1944. Compiled by Oliver E. Byrd. Foreword by C. Morley Sellen, M.D. Pp. 354, 13s. 6d. California: Stanford University Press, London: Oxford University Press.

This yearbook consists of abstracts of 305 articles appearing in various American periodicals in the years 1943 and 1944. It is intended for health instructors and students of current health problems, and not for technically trained persons. As its author, Prof. Oliver E. Byrd, points out in his preface, it does not attempt to give a complete summary of health literature, but it is designed to be an annual publication, so the series will become useful for reference purposes. Though the volume under review is inevitably disjointed, it forms a much more readable account of health instruction than might be surmised from the method of its compilation. This is owing to the fact that the author has classified his information in 20 fairly well defined chapters, and he has usually abstracted, at some length, the introductory remarks in the various articles dealt with.

The first two chapters relate to health as a social problem, and the next chapter to health in relation to nutrition. They are followed by chapters on the effects of exercise and body mechanics, and on mental health and disease. The longest and most interesting chapter in the book relates to infection and immunity, with extensive references to penicillin. The commercial production of this substance in America may be gauged by the fact that the output increased more than twentyfold between June and December, 1943, while in March, 1944, it was twice the 1943 total. By then there were 18 plants for its manufacture in the United States and two in Canada.

Another topic dealt with at some length is the Kenny method for treating infantile paralysis. In a chapter on habit-forming substances we learn that the yearly *per caput* consumption of cigarettes in the United States is now 1,880, and is 60 times greater than in 1900. The consumption of alcohol is likewise rising rapidly, being 17% greater in 1943 than in the previous year. In the chapter on "Safety" we learn that nearly 100,000 persons are killed each year from all types of accidents, and 10,000,000 are injured. Factory accidents increased twice as fast in proportion to the extra number of persons employed, and they have been a major source of impairment of war production. A long chapter on health in relation to physical environment discusses frost-bite, immersion foot and trench foot, and, at the other extreme, the reactions to desert climates and heat-stroke. Three of the subsequent chapters deal with family health, school health, and occupational health, and there is a final chapter on "Trends and Probabilities," which refers in some detail to the White Paper on Britain's National Health Service, and discusses related problems in Canada and the United States.

PROBLEM FAMILIES

Problem Families: An Experiment in Social Rehabilitation. Edited by Tom Stephens. (Pp. 72; illustrated. 2s. 6d.) London: Pacifist Service Units, 6, Endsleigh Street, W.C.1. 1945.

This pamphlet is an account of some of the most difficult, unpleasant, and thankless work ever undertaken by social reformers. In every large town there exists what Charles Booth called the "submerged tenth"—a kind of social sediment of persons and families, either mentally defective or subnormal in some other way, living from hand to mouth in filthy hovels, a prey to disease, crime, and vice. These apparently irreclaimable outcasts are the object of some admirable case-work done by three small groups of voluntary workers—the Pacifist Service Units in Liverpool, Manchester, and Stepney—who have tried to bring them whatever help could be devised, to enable them to reach satisfactory living conditions, and to restore them—or elevate them for the first time—to self-respecting citizenship. General improvement in living conditions passes such families by, for their peculiar characteristic is their inability to use the facilities and services which are made available for them. Most of the 62 families studied by the units had been given up by other bodies as hopeless. The majority are housed in old insanitary property or unfurnished rooms, the neglect and disrepair of which are largely due to misuse by the tenants. Parents, children, and babies sleep huddled together in one filthy bed. The most obvious common feature of these families is the disorder of their lives—time and duty mean nothing to them. The children are sent to school late, unwashed and ill clad, and run wild in the streets when they are out of school. The cost of these families to the community in social service is quite disproportionate to their numbers, and they produce most of the juvenile delinquency and dirt diseases. This book is not a survey of the problem, which has never been properly studied, but a moving account of some real work at its centre.

The units, each consisting of a field-work leader, a secretary, and a team of case-workers, have struggled not only with the families but with their own lack of means and help and with the efforts of the Ministry of Labour to direct them to other work. The pamphlet tells the story of their results, and that they should have done so much is miraculous. The book is illustrated with six well-chosen photographs which bring out dramatically the squalor of these people and their surroundings. It provides an overwhelming argument for a purposeful dealing of this lamentable problem by the agencies of central and local government, who have hitherto managed to evade it.

PAEDIATRIC RADIOLOGY

Pediatric X-ray Diagnosis. A Textbook for Students and Practitioners of Pediatrics, Surgery and Radiology. By John Caffey, M.D. (Pp. 838; illustrated. \$12.50 or 75s.) Chicago: The Year Book Publishers; London: H. K. Lewis and Co.

Those who are especially interested in paediatrics are fond of asserting that it is not a specialty but rather an application of the principles of general medicine and surgery at a special age period. In x-ray diagnosis this is well illustrated, for the essential problems and difficulties are occasioned by the age

of the subjects and the rapid changes caused by growth and development. Dr. John Caffey, who is the associate professor of paediatrics at Columbia University, is also associate paediatrician and radiologist to the Babies' Hospital, New York. He has written a textbook called *Pediatric X-ray Diagnosis*, which he claims is the second only of such books in the English language. It is based on fortnightly conferences at the Babies' Hospital during the last twenty years, and Prof. Rustin McIntosh has read and criticized the entire manuscript, so that the standard of the whole book is high and clearly based on wide experience. The subject-matter is arranged anatomically in six main sections: head and neck, thorax, abdomen, pelvis, extremities, and vertebral column. The paper used allows of reproduction in the text of the illustrations, over 700 in number, and the choice has been well made, arrows and diagrams being used whenever necessary to bring out important points. There is a good index.

Students and practitioners of paediatrics, surgery, and radiology will find this a valuable work of reference. Its appearance fifty years after Röntgen's discovery is a remarkable example of the developments of this indispensable aid to diagnosis.

Notes on Books

The fifth edition of P. N. PANTON and J. R. MARRACK's *Clinical Pathology* (London: J. and A. Churchill; 21s.) has been revised with the assistance of H. B. May. There is a new chapter on anti-bacterial chemotherapy, and various new methods are described, particularly in haematology and chemical pathology. This well-known little book serves as an attractive introduction to the various branches of its subject, and will assist practitioners as a reference book in connexion with pathological investigations. The sections on bacteriology and morbid histology, though excellent as far as they go, need for the student's purposes to be supplemented by the use of other textbooks on these subjects.

The fourth edition of J. A. KOLMER and FRED BOERNER'S *Approved Laboratory Technic* (London: D. Appleton-Century Co.; 50s.) appears after an interval of four years, and has been extensively revised. This comprehensive and profusely illustrated work describes a great variety of methods, and the clinical pathologist faced with an investigation with the details of which he is unfamiliar will find it a valuable work of reference.

Vol. III of *Selected Papers from the Royal Cancer Hospital (Free)* and the *Chester Beatty Research Institute* comprises reprints of 39 articles by members of the staff which appeared in various medical and scientific journals during the years 1941 and 1942. It runs to 350 pages and includes many illustrations. In a brief foreword the Governors of the hospital acknowledge generous financial support from bodies both in this country and in the United States, without which the researches described would have been impossible. The British Empire Cancer Campaign has made substantial grants every year since its foundation in 1924. Gratitude is expressed to the Sir Halley Stewart Trust, the Medical Research Council, and the Laura de Saliceto Fund of the University of London; also to fellow-workers in cancer research in the U.S.A.—namely, the International Cancer Research Foundation, the Anna Fuller Fund, the Jane Coffin Childs Memorial Fund, and the Finney-Howell Foundation. Copies (price 16s.) may be had from the Secretary of the Royal Cancer Hospital, Fulham Road, London, S.W.3.

Néphropathies et Néphrites, Leçons Cliniques, by F. RATHERY, is published in Paris by Librairie J.-B. Baillière et Fils, 19, Rue Hautefeuille. These clinical lectures were given in 1937-8, but they were not published till 1941 and have only now made their way to this country. They deal with a variety of topics from the role of sodium chloride in nephritis to carcinoma of the kidney, and they make pleasant and informative reading for the student of renal disease. Until recent years, at any rate, the French approach to nephritis has been more dynamic and functional than ours, and it is well depicted in these lectures.

Methods for the further reduction of smoke in towns and its prevention in new building areas are detailed in a booklet which the National Smoke Abatement Society has prepared for local government authorities. It is pointed out that legislation in respect to smoke has so far been punitive and concerned only with mitigating a nuisance already committed. Responsible opinion is now in favour of legislation that is preventive and concerned with conditions resulting in smoke. The booklet urges that plans and specifications of all proposed new fuel-burning plant should be approved by a competent authority before installation, and local authorities should set an example by ensuring that their own premises, and premises under their direct control, are rendered smokeless.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 2 1946

PRINCIPLE AND UNITY

Medical men at the moment have a natural impatience with the absence of information about medico-political developments. It is rather like waiting to hear the result of the final examination. Mr. Bevan has made his statement about the buying and selling of practices. His draft proposals have been submitted to the principal interested bodies. The irksome question of compensation is now under discussion, and at the same time the Spens Committee is completing its investigation into the incomes of general practitioners. The Negotiating Committee, representative of all groups of medical men and women, has been hard at work examining the Government's proposals and thrashing out the question of compensation. Why cannot we be told what is going on? is the question that naturally comes to all those who personally have so much at stake, and so many immediate and remote decisions to make—whether to retire in the assurance that practices will be sold either to an individual successor or to a Government which will pay full compensation in hard money, or whether, for the young man, to buy a practice now or wait in suspended idleness. If there is a silence on these matters it is a silence imposed by the necessities of the situation. The Government's provisional plan cannot be discussed because it has been submitted as a confidential document on which the Negotiating Committee, among other bodies, is asked for its observations and comments. The committee will no doubt ask the Minister a number of questions on a great many points of the plan, and will criticize many aspects of it in the light of the principles published in the *Journal* of Dec. 15 (p. 833). These criticisms and questions will also be based on previous decisions taken by the profession, and, in the case of the B.M.A., on policies laid down by the Representative Body. The Negotiating Committee has no mandate to go further than this, and cannot commit the profession to the plan in part or in whole. It can but criticize and comment and then wait to see whether the Minister will take notice of its representations when he presents a Bill to the House of Commons. At this point the medical profession will have to examine the contents of the Bill in a critical, thoughtful, but dispassionate spirit, and decide what its attitude is to the Bill as a whole and to its various parts. The task of the Negotiating Committee will be to collect the opinions of the profession, to analyse these, to sift out the implications of the Bill, to formulate what comes out as the considered judgment of the profession, and then to decide with the majority what action to take. After all, unless the profession decides to operate the projected service, legislation will remain a dead letter.

In this very critical phase of the history of medicine the profession is faced with two distinct dangers, and it will be according to how it faces these and masters them that it will be in a position to guide its own destiny in working

out a comprehensive health service in co-operation with a Government recently elected by the people of this country. The first danger is that the profession will fail to be really united on the basis of common objectives and on agreement on the means of reaching these. The second is that the spirit of demagoguery will prevail, and that in the confusion of emotional tongues the small voice of reason will be drowned beyond hope of resuscitation. There is a real risk that shibboleths and slogans will be substituted for reason and fact, that many of us will behave as thalamic rather than as cerebral animals. Nothing can do greater disservice to the real interests of medicine than the use of emotive words and phrases, and indulgence in the language of the hustings. To bandy words like "Fascist" and "Communist," "reactionary," and "revolutionary," or to indulge in vituperation against persons, institutions, or parties, will belie our claim, and our just claim, to be considered as a learned and liberal profession, whose thought and way of life are based upon science and the humanities.

The expression is often enough heard that we are a divided profession, and that our divisions are obscured by a polite convention not to refer to them. The Minister himself has hinted that our divisions are deep, and as an experienced politician he may be expected not to ignore the divisions if they may help him in achieving what he believes to be desirable for the health service it is his task to provide. *Divide et impera* is a familiar maxim for those in power. We must recall that the Minister has an obligation to fashion a national health service. It is a policy that was agreed on by all parties in the Coalition Government, and successive plans were made by and negotiations conducted with first a National Liberal, then a Conservative, and now a Labour Minister. The profession cannot put the clock back or stop it from ticking on—even though to some it may now seem like an alarm clock timed to go off at any moment in the next few weeks.

A disadvantage under which the profession labours is that there are so many diverse activities and interests within it. It is, in a way, compounded of many professions. Although all the various professional groups are united by a common educational background and a common aim to relieve the sick and the suffering and to promote conditions of health, there are many sharp antagonisms within it, and many different ways of life. There is, for example, a great difference in the way of life and work between the hard-worked panel doctor in a poor industrial district and the successful consultant in London, between the general practitioner and the medical officer of health, between the medical superintendent of a municipal hospital and a research worker in a clinical unit, between the medical administrator and the industrial medical officer, between the ship surgeon and the medical statistician. It is, in fact, one of the highest attractions of the profession of medicine that it offers such a rich variety of life for so many different types of men. But this very diversity makes unity difficult. It seems at times that each group, each unit, and even each individual, wants a medical service to suit it or him. As Sir George Stapledon said about another matter in a recent letter to the *Times*, "It will be well if those responsible never for a moment permit themselves to forget that

regimentation is foreign to the British character, for at heart we are a race of pirates, individualists, adventurers, and inspired amateurs." This is something the Minister must take into account if he is to secure the co-operation of the medical profession, and it is something the profession itself must take into account if it is to secure the unity which alone will lend wisdom and direction to its decisions and actions.

It is safe to prophesy that, whatever provisions the coming Bill will contain, some members of the profession will be dissatisfied. And it is clear that no counter-proposals will secure the assent of every doctor in the *Register*. For example, the small but active group represented by the Socialist Medical Association will be content with nothing that stops short of the socialization of medicine, and we may assume that their political aims—if not their present programme—coincide with those of the present Government. In opposition to this will be those who in politics are conservative. But probably the mass of doctors are non-political in attitude and want only to get on with their work in their own way with the least possible interference from anyone else.

On what basis, therefore, can we seek unity? It cannot be on a basis of expediency and stratagem, but on the basis of principle. The Negotiating Committee has given a clear lead by enunciating certain principles and by publishing them. These have been accepted and approved by the profession with scarcely a voice of dissent, and it is appropriate to repeat here the principles which stand out as embodying what is sincerely held by the overwhelming majority of doctors in this country.

I. The medical profession is, in the public interest, opposed to any form of service which leads directly or indirectly to the profession as a whole becoming full-time salaried servants of the State or local authorities.

II. The medical profession should remain free to exercise the art and science of medicine according to its traditions, standards and knowledge, the individual doctor retaining full responsibility for the care of the patient, and freedom of judgment, action, speech, and publication, without interference in his professional work.

III. The citizen should be free to choose or change his or her family doctor, to choose, in consultation with his family doctor, the hospital at which he should be treated, and free to decide whether he avails himself of the public service or obtains independently the medical service he needs.

IV. Doctors should, like other workers, be free to choose the form, place, and type of work they prefer without Governmental or other direction.

V. Every registered medical practitioner should be entitled as a right to participate in the public service.

VI. The hospital service should be planned over natural hospital areas centred on universities, in order that these centres of education and research may influence the whole service.

VII. There should be adequate representation of the medical profession on all administrative bodies associated with the new service, in order that doctors may make their contribution to the efficiency of the service.

These are not just idle words thrown together to create an impression of general high-mindedness. They are the reagents with which we must test the Government's mixture. Each item of the Bill must be examined in the light of these principles, and so must the Bill as a whole. If there is any fundamental departure from these principles,

then resistance to what offends against them will be firmly based. To resist on any other basis would be folly. Conversely, if the Government can convince the profession by reasoned argument and agreed adjustment of differences that these principles will not in fact be infringed, then the profession will not wish to withhold its co-operation in the task of remoulding the medical and health services of Great Britain.

COMPENSATION

The Negotiating Committee has met the Minister of Health been informed of his proposals, and been invited to comment on them. Since meeting the Minister it has met three times to consider his proposals and prepare its comments on them. It will meet the Minister again next week and convey its views to him. Simultaneously, discussions have been going on between a special subcommittee of the Negotiating Committee and officials of the Ministry of Health on questions of compensation. Neither the Negotiating Committee nor the Compensation Subcommittee can commit or has committed the profession to an acceptance of the Government's view that the buying and selling of practices shall cease. This question is on for the profession to decide when it sees the Government's proposals as a whole and the compensation and other proposals indicated. Subject to this important reservation discussions on the details of compensation have been proceeding, and it is probable that a statement of the Government's intentions will be made at an early date. The announcement will take the form of a statement of the Government's proposals. The reply of the profession will be made on the plan as a whole soon after the Bill published.

SULPHONAMIDE CONTROL OF STREPTOCOCCAL EPIDEMICS

War entails the crowding together of great numbers of men, and crowding favours the spread of infection. In 1918-19 haemolytic streptococcal infections caused 242,000 casualties in the American armed Forces, and 56,000 men were crippled with rheumatic fever or acute rheumatism. At the onset of World War II greater precautions had been taken against respiratory infections. Nevertheless in 1919 the haemolytic streptococcus caused 47,000 infections in the United States Navy, and in 1943 the rate continued to rise among the large numbers of new recruits stationed at the great training camps. In November, 1943, a "Streptococcal Control Programme" was instituted, and its methods and success have recently been described by Coburn.¹

Owing to the military needs of the moment many recognized methods for the control of streptococcal epidemics—e.g., isolation of carriers—were impossible, and from the start emphasis was placed on continuous chemoprophylaxis. This was effected by giving every man 1 g. of sulphadiazine daily. At first only half the men in each camp were treated in this way, and the other men were retained as controls. But in a few months the success of the measure was so clear that the treatment was extended to all the occupants of the camps. Altogether 600,000 men were given prophylactic sulphadiazine in this way for a total period of 3,000,000 man-weeks. The treatment was maintained for most of the winter, when the risk of infection was high. Haemolytic streptococcal infections were

¹Bull. N.Y. Acad. Med., 1945, 21, 281.

greatly reduced, and the hospital admission rates for respiratory diseases fell from 5 to 18 per thousand men per month in the different camps to less than 1 per thousand. Illnesses due to scarlet fever, to tonsillitis, or to rheumatic fever were all much diminished. Instead of the carrier rate for haemolytic streptococci among new recruits becoming almost 30% it remained constant at its previous level of about 10%. The success with other infections depended upon the sulphonamide-sensitivity of the relevant organisms. The meningococcus was highly susceptible, and meningococcal meningitis was practically abolished. The pneumococcus varied in sensitivity in different camps: in some the disease rate fell by 50 to 80%; in others it was unchanged. Virus diseases, such as influenza and measles, were unaffected. The daily dose of 1 g. of sulphadiazine resulted in a mean blood concentration of about 2 mg. per 100 c.cm. This dose was slightly more effective in preventing infection than a dose of 0.5 g. daily. Toxic reactions were much less frequent than had been feared; about 0.5% of the men had mild dermal reactions during the first three weeks. Severe reactions, such as granulocytopenia or exfoliative dermatitis, occurred in only 39 men out of the 600,000—less than 0.01%. These severe reactions were reversible provided that the patients were not given further sulphonamide treatment. Before this was realized there were 13 deaths due to sulphonamides. Later penicillin therapy was instituted for such cases, and there were no further deaths. These casualties should be balanced against the greater number of deaths which might have been caused by streptococcal infections if the disease rate had not been controlled. Mass chemoprophylaxis did not induce sulphonamide-hypersensitivity among the men, nor did it produce sulphonamide-resistant strains of streptococci. Altogether this experience forms one of the most successful medical operations of the war.

Its applicability to peacetime practice is less straightforward. The conditions under which it was so successful were peculiar in many ways. These training camps formed closed communities, shut off from the rest of the world except for the continuous addition of non-immune recruits. The population consisted of young men from different localities, each exposed to many infections not previously encountered. Because of crowding in the barracks, swimming instruction in indoor baths, etc., the risks of transmission of infection were much greater than is usually the case. Finally, a high proportion of the respiratory infections were due to the haemolytic streptococcus, an organism particularly sensitive to the action of sulphonamides. In peacetime sulphonamide prophylaxis will be most effective in relatively closed communities—e.g., residential schools or large mental hospitals. Factories or offices appear unsuitable because the worker mingles with all sorts of other people for the non-working part of the day. Secondly, this measure should be limited to epidemics known to be due to a sulphonamide-sensitive organism; the sulphonamide-sensitivity of the predominant organism should be examined as early as possible. Sulphonamide prophylaxis is also justified for persons who have suffered from rheumatic fever. These people are so susceptible to infection by haemolytic streptococci, and the consequences of such infections, which reactivate the rheumatic process, are so harmful, that the risk of toxic reactions might well be taken in order to avoid the much greater risk from further attacks of rheumatic fever. Special supervision should be provided for all these groups to detect and to treat any untoward reaction to the drug. Further details about the indications for such chemoprophylaxis, and its general conduct, are given in a recent Medical Research Council memorandum.²

ATOMIC RESEARCH AND MEDICINE

In his recent address to the Manchester Joint-Research Council Sir John Anderson mentioned the usefulness to medicine of work on the atomic bomb. The technique employed to produce the new element plutonium gave a ready means of procuring a vast range of new radioactive substances. Radio-phosphorus, radio-iron, and radio-sodium, for example, could now be administered in proportions too small to be harmful, and their radio-active properties could be used to determine their exact behaviour in humans and in animals. Work of this kind has been done in many laboratories in the United States during the last five years.

One of the striking developments has been the discovery of the mechanism of transmethylation by Vincent du Vigneaud at Cornell University Medical School in New York. His work leads to the general conclusion that all C-CH₃ and S-CH₃ groups in the tissues of the body originate in the methyl groups of choline, betaine, and methionine.^{3,4} He studied the effect on the growth of rats of adding homocystine to a methionine-free diet. Some observers had found that homocystine enabled rats to grow, but du Vigneaud was unable to confirm this. He showed that something in the B complex was necessary as well as homocystine, and finally choline was discovered to be the missing substance. In the presence of choline, homocystine was transformed to methionine, and this effect of choline was because of the methyl groups it contained; tri-ethylcholine had no such effect. Thus the inference was that the growth which resulted from feeding both homocystine and choline was due to the transference of a CH₃ group from choline to homocystine to yield methionine. Proof of this was obtained by preparing choline in which the hydrogen in CH₃ groups was replaced by heavy hydrogen (deuterium). This product, deuteriocholine, was fed to rats together with homocystine; du Vigneaud then sought and found the deuterio-methyl group in the methionine of the tissues. He has shown in the same way that the methyl group of creatine comes from choline or methionine; deuterio-choline given to rats led to the appearance of the deuterio-methyl group in the creatine of the muscles and also in the creatinine of the urine. This observation has since been extended to man by feeding heavy methionine and examining the creatinine in the urine. The administration of heavy methionine to rabbits leads to the appearance of deuterio-arsenine in the muscle tissue. Dr. George Whipple and his colleagues^{5,6} have used ferric sulphate, ferric chloride, and ferric ammonium citrate containing radio-active iron; the amount present might be 1 part in 2,000 million. They have given a single dose of this so-called "tagged" iron to dogs depleted of iron. This leads to a rise in the proportion of red cells containing tagged iron which reaches a peak between the fourth and the seventh day, after which the proportion declines. If red cells are broken down by giving acetyl phenyl hydrazine it is found (by following the tagged iron) that the iron set free is almost wholly used to make fresh red cells. In dogs with a biliary fistula very little iron is found in the bile; the amount may rise from 0.2 mg. to 2 mg. for a day or two and then diminish, the total iron excreted in the bile being about 15 mg. The total breakdown, however, has been about 450 mg. The formation of liver glycogen in the rat after the administration of lactic acid has been studied by Baird Hastings at Harvard.^{7,8} There are three carbon atoms in lactic acid, and samples of lactic acid

³ *J. Biol. Chem.*, 1939, 131, 57.

⁴ *Ibid.*, 1941, 140, 625.

⁵ *Ibid.*, 1940, 134, 555.

⁶ *Amer. J. Physiol.*, 1942, 135, 600.

⁷ *J. Biol. Chem.*, 1941, 137, 557.

⁸ *Ibid.*, 1942, 142, 371.

have been prepared in which each of these three carbon atoms in turn was radio-active. Thus it has been possible to find to what extent the three carbon atoms respectively contribute to the formation of liver glycogen.

These examples of the use of radio-active elements can be multiplied many times. Thus observations in which radio-active iodine and radio-active phosphorus have been employed have been made by several workers. It is clear that the method provides a new approach to the discovery of the stages of numberless biochemical transformations.

A MODERN VIEW OF GOUT

Most physicians in this country would describe gout as a disease of the past, like chlorosis and abdominal aneurysm, and it is therefore interesting to read an American monograph which strongly controverts this and other views about the disease.¹ Talbott claims that gout is not rare, accounting for 5% of all patients suffering from disease of the joints, and there is no significant reduction in incidence from generation to generation. He uses the word "gout" as a parent term with three clinical subdivisions: acute gouty arthritis, intercritical gout, and chronic deforming gouty arthritis. This implies that gout, in the sense of a disturbance in the metabolism of uric acid, may be latent or subclinical, and family studies show that this is indeed the case. A high proportion of the relatives of patients with gouty arthritis have an abnormal amount of uric acid in the serum, although they themselves may not have suffered from joint symptoms. Gout is in fact a hereditary disease, and as it occurs twenty times as often in males as in females it may be a sex-linked characteristic. Cases of gouty arthritis develop in gouty families primarily because of the hereditary predisposition, while social factors, environmental influences, and dietary indiscretions are relegated to a position of secondary importance. There is no support for the view that gout is confined to the upper social strata or that it is a disease of persons who are habitually intemperate, whether in regard to alcohol, sexual activity, or food. In estimating uric acid it is important to use plasma or serum rather than whole blood; with this precaution values over 6 mg. per 100 c.cm. of serum are found in 96% of cases of gout, whereas they are extremely rare otherwise. Chemically it is more accurate to speak of urate than uric acid, as the acid cannot exist in a free state in the body fluids. Studies of the renal clearance by modern techniques show that there is no significant difference between gouty and non-gouty subjects in the ability of the kidney to excrete urate. The corollary appears to be that the disease is due to an increased formation of urate in the body. This metabolic error probably exists from birth, but gives rise to symptoms only in later life and in a small percentage of those with the defect. The renal damage which is so common a feature of advanced gout is the result of the excretion of insoluble urates which are precipitated in the tubules and damage kidney. In fact the gouty kidney might well be compared with the sulphonamide kidney.

The nature of the acute attack of gout is not clearly understood, but it is probable that crystals of sodium urate are deposited from the synovial fluid on to the surface of the cartilage. Although the attacks are often attributed to eating and drinking, there is little scientific evidence that this is the case, though some patients learn to recognize that specific articles of food or drink may bring on an attack. On the other hand it has been shown that certain drugs may be responsible, such as liver, vitamin B,

salycan, insulin, and ergotamine; so also may acute infections, trauma, and surgical operations. Many atypical and aberrant forms of gout have been described, but these are for the most part mythical maladies. In fact, gout, like malaria and influenza, has often served as a cloak for ignorance; but the biochemical test for the uric acid in the blood has removed any excuse for confusion. The specific remedy for gout is colchicine, which is both highly successful in effect and mysterious in mode of action; it does not increase the excretion of urates. Talbott emphasizes how important it is for patients to take colchicine early and in adequate dosage when they experience the symptoms which they have learned to recognize as the prodromata of an attack. He advises a tablet of 0.5 mg. colchicine alkaloid every 60 or 90 minutes until relief has been obtained, or 16 tablets have been taken, or gastro-intestinal irritation prevents further dosage. Usually joint pain begins to subside in 12 hours and relief is complete in 24 to 48 hours. Small doses of colchicine are useful in the intercritical periods but here salicylates also have a useful place. Salicylate and diodone increase the excretion of urates by competing as it were, for the activity of the tubule cells; salycan and cinchophen act by depressing the function of the tubule cells and preventing reabsorption of urates. Talbott recommends colchicine and salicylates as the basis of medical treatment, and condemns the use of cinchophen as unjustifiably dangerous. His monograph is beautifully illustrated though one would have liked to know the magnification of the photomicrographs, and in its clear style and presentation it is a noteworthy contribution to the literature of gout, a disease which has always had an attraction for the medical stylist.

THE CHRONIC SICK

In all the hospital surveys, issued in conformity with the Ministry of Health decision in 1941 to examine the hospital services of the whole country, the one unanimous recommendation concerns the chronic sick. All the surveyors seem to have been impressed by the deplorable lack of accommodation or the poverty of the accommodation for this unfortunate class of people. There are exceptions in progressive towns, but in general the oldest and worst buildings seem to be assigned to these patients. Most of the surveyors recommend strongly that no chronic sick person should be admitted primarily into a hospital or institution designated for the sole treatment of such cases. Some of them want to do away with the term "chronic sick" altogether, because the label becomes tantamount to "incurable." One proposal is that the provision for the chronic sick should never be divorced from the general hospital, but that these patients should be housed in separate blocks within its curtilage. It is suggested that in some areas most of the public assistance institutions should be scrapped and rebuilt. The number of chronic sick is variously given; one estimate is 2 per thousand of population. But however many there are this does seem to be the Cinderella of hospital administration, and the subject will need special attention in the Government's plans.

We much regret to announce the death of Sir Comyn Berkeley, consulting obstetric and gynaecological surgeon to the Middlesex Hospital and Chairman of the Central Midwives Board; also, on the same day and at the same age, of Sir John Broadbent, Bt., consulting physician to St. Mary's Hospital and for ten years Dean of the Medical School.

PREMEDICAL ZOOLOGY: A DIFFERENT VIEW-POINT

BY

D. W. EWER, M.A., Ph.D.

The problem of the early biological instruction of medical students has been the subject of a recent interesting and stimulating article by Drs Abercrombie and Johnson.¹ With their ideas on how to train young students in scientific method no one will quarrel. Many of their ideas about the reform of the zoological syllabus of the first M.B. examination are, however, more controversial. Their central theme is that the proper study of the elementary medical (and zoological) student is man, and that zoological instruction given during the first year at university or hospital should be redesigned along these lines.

The need for the extension of biological teaching in schools is now generally accepted and there can be little doubt that for those who do not intend to pursue biological studies further the biology of man must receive first consideration. For those who are going to dedicate many years to the subject the anthropocentric approach may not be the best starting point. The medical student will devote two years to the unrestricted study of human anatomy and mammalian physiology and will subsequently study the human body in disease. Since all his later student years are to be dedicated to the study of biology from this limited view point the need for giving him during his first year as broad a background as possible is imperative.

Man's Place in the Evolutionary Scheme

The zoological training of the first year medical student has to be considered with two factors in mind.

(i) The course must lay a scientific foundation for a highly detailed study of human anatomy and physiology. It must therefore include a general outline of mammalian anatomy (including histology) and physiology, and also, since it is widely used for physiological experiments, the anatomy of the frog, the use of the microscope and of the scalpel must also be known.

(ii) The medical student will usually not have an opportunity for the further study of zoology. The course must therefore make it clear that one scientific approach to human anatomy and physiology lies in an understanding of man as the product of long evolution and as adapted to a particular habitat. At the same time the scientific principles underlying the study of the relationship of man to his civilized environment, to his parasites and his food supply, must be made plain.

These considerations closely define the nature of the course which is required. The central theme must be that of evolution rather than man. Nothing in fact, could be more unfortunate scientifically than to inculcate in the mind of the young student the idea of man as the measure of all things. It is true that man may be better in this role than the traditional frog but, as Prof Cole's recent *History of Comparative Anatomy* shows clearly, this approach is scientifically barren, and biological thought without the guiding principle of evolution becomes pointless and undirected.

The existing syllabus was no doubt framed with the idea of illustrating evolution. The method used is to give a short description of the whole animal kingdom illustrated by a detailed study of a few animal types. Unfortunately the account of the anatomy of the types has tended to become an end in itself, and the underlying principles, hard enough to appreciate anyway in such a broad survey, have been lost. The method is a failure, and has led to the student cult of the reproductive organs of the earthworm whose ending no one could lament.

Outline of Vertebrate Evolution

It is clearly necessary to reform the course. How, then, in greater detail should this be done? A start should be made with a survey of the animal kingdom in relation to habitat and structure. This must not, however be allowed to descend to the level of a catalogue of aesthetically pleasing or economically important animals. It must show clearly how, say, arthropods differ from molluscs and echinoderms. The principle of increasing complexity of structure must be stressed but no time should be spent on the detailed anatomy of

particular invertebrates. Then, by reference to the fossil record the general outline of vertebrate evolution should be shown as demonstrated on the one hand the fact of evolution and on the other the biological position of man as a recent product of a long process. The course should then give a detailed account of the evolution of the vertebrates as a dynamic story showing the fish as the starting point, how and why the vertebrates came on land, the real problems they had to solve and how these were solved increasingly effectively by amphibians, reptiles, and mammals.

This treatment differs from that of Drs Abercrombie and Johnson very radically. They believe that the principles of comparative morphology are the "least important branch of zoology when man is the centre of interest." Surely it is these principles which can help to lighten the long study of zoographical anatomy. To omit these, the greatest unifying principles of biology, is to encourage an empirical and unscientific frame of mind. It is because these principles are so well illustrated in any account of the evolution of the terrestrial vertebrates that particular emphasis has here been laid on this question.

If the principles of comparative morphology are rejected a new unifying idea has to be sought. This is found by Drs Abercrombie and Johnson in a "central theme, such as the maintenance of constancy of the internal medium in the land habitat." This theme is to serve as the leitmotiv to a study of the physiological anatomy of man against a background of other animals.

It is submitted that this central theme is asking the student to run physiologically before he can walk. The maintenance of the constancy of the internal environment is effected by the integrated regulations of certain functions. Before these regulations can be understood the methods of working of the component parts must be thoroughly grasped, and in some cases a very detailed knowledge is required. The elementary student must be given elementary facts, and would surely be better served if he is shown the fundamentals of certain types of physiological mechanisms such as locomotion, digestion, respiration and excretion if he is shown the living organism as a physiological unit and as an attempted adaptation to a particular way of life. The essentials of the various mammalian physiological mechanisms and their anatomical basis can undoubtedly be better understood when they are seen in relation to the evolution of the terrestrial vertebrates, rather than when odd animals are occasionally introduced to clarify particular difficulties which may arise in human anatomy and physiology.

The treatment of vertebrate embryology should go hand in hand with that of anatomy and physiology, and the adaptations of the embryo to a terrestrial existence should be shown. At the same time the significance of recapitulation and its usefulness in understanding the morphological events of ontogeny should be explained.

The course of study should then proceed to consider the possible mechanisms of evolution, genetics should be shown in its relation to natural selection. The question of nature and nurture can be amply discussed in this connexion as well as the evolutionary consequences of tool using and civilization. Here also logically belong a discussion of adaptation and ecology including food-chains and the pyramid of numbers together with a consideration of the effect of human interference on animal populations. The problems of the biology of parasitism should be presented against this background, emphasis being laid on how control measures are dependent on a knowledge of the biology of the parasites and their hosts rather than on over-detailed accounts of the morphology of different stages in the parasite cycle. Finally a brief account of the historical development of biology should be given so that its relations with medicine and the other sciences may be seen. These latter details agree closely with the proposals of Drs Abercrombie and Johnson in content except that the emphasis on evolution rather than on man is still stressed.

Social Aspects of Science

During recent years there has grown up an increasing body of opinion which believes that the interest of the student in science can be enhanced if the social applications and origins

¹ Abercrombie M. and Johnson M. L. *British Medical Journal* 1945 2 522.

of the subject are emphasized. This view is doubtless quite correct, but is open to abuse and misinterpretation. For example, it is not necessary or desirable to teach only the latest discoveries in any field. Physics is not best approached through atomic bombs, or biology through D.D.T. In dealing with embryology Drs. Abercrombie and Johnson suggest that the course should consist of "development, omitting details of morphological embryology." This is a vague formula, but when taken together with their dictum that "comparative morphology is the least important branch of zoology," one wonders whether the morphological details are to be replaced by a discussion of the results of experimental embryology. Interesting and important as these are, they are certainly incomprehensible without a detailed morphological background. Students may perhaps learn the catchwords, but their knowledge will be shallow.

Again, the introduction of the social aspects of science cannot eliminate the necessity for application and learning on the part of the student. The multiplication tables still have to be learnt even if their historical background is explained; they are no easier to learn because of it, but the incentive to learn may be greater. Such an approach must not be allowed to become one in which learning the social background replaces learning the facts; mathematics, chemistry, and zoology must not be allowed to degenerate into history and sociology.

Finally, such an approach must not be used as an excuse for learning something different simply because it is easier. This appears to be the attitude of Drs. Abercrombie and Johnson. In defence of their anthropocentric orientation they stress the point that "the material [presented] will be more readily learnt and retained than will that of traditional zoology." Note that the contrast is between traditional zoology and human biology, not between the traditional presentation of zoology and a presentation with a more human appeal. Drs. Abercrombie and Johnson in fact favour human biology rather than zoology as a part of the early training of the medical student because, *inter alia*, they find that human biology is easier to learn than zoology. To learn Spanish is probably easier than to learn Greek; both may be necessary, but they are not the same thing. This appeal to ease of learning must be disallowed, though it is incidentally interesting to note in this connexion that the B.B.C.'s biological course for schools, prepared by Miss Honor Wyatt, has for several years now been based on the story of vertebrate and human evolution.

Another argument pressing the claims of human biology is that it will forge a real link between the first M.B. and the subsequent course, so that there will be "less danger that the biological principles which the course illustrates, and the scientific attitude it is supposed to inculcate, will be jettisoned." It is not clear why Drs. Abercrombie and Johnson consider that the inculcation of the scientific attitude ends with the first M.B. That, however, is beside the more important point that this link depends in reality on the fact that the biological principles which Drs. Abercrombie and Johnson would introduce into the first M.B. are those which the students will have with them always. I suggest that the link should in fact be forged from the other side and that more material from comparative anatomy and physiology could advantageously be incorporated in the second M.B. courses.

Conclusion

In the final analysis, however, we return to the problem of whether there is a need for a zoological course for first-year medical students or whether they should rather be given an outline of human biology, including instruction in human anatomy and physiology, presumably by competent human anatomists and physiologists and not by zoologists, whose knowledge and experience on these matters are generally limited to their reading of textbooks. It has been urged above that the contribution of zoology to the intellectual armament of the medical student is the evolutionary outlook towards biology. This, zoology alone can give, and if this, the most embracing of all biological generalizations, is worth fully understanding, the medical student must have a zoological course. To sum up:

(i) The main contribution of zoology to the intellectual training of the medical student is the idea of evolution.

(ii) The zoological course of the first M.B. should be designed to show man's place in the evolutionary scheme.

(iii) This can most easily be done by laying the main emphasis on the evolution of the vertebrates.

(iv) A course in human biology is not a substitute for a course in zoology, nor is ease of learning a criterion by which the desirability of teaching a subject can be judged.

ORGANIZATION FOR TREATMENT OF CANCER

Some three years ago, as a sequel to the passing of the Cancer Act, the National Radium Commission issued a pamphlet *Organization for the Treatment of Cancer*. The Commission did not attempt to frame an exact constitution, nor did it lay down any specific pattern for future organization. It confined itself to an examination of the defects of existing facilities for dealing with the disease, and put forward suggestions for the improvement of these, dealing, however, with general principles only; for example, the importance of early diagnosis, the need for consultation between a team of experts before treatment is planned, the desirability of pooling resources, and the cardinal position occupied by research. The Royal Cancer Hospital (Free) found itself in general agreement with the Commission, having already been working for some years on the lines recommended. It was thus encouraged to develop its plan. Some two years later a second pamphlet, known as *The A B C Scheme*, was published. This went into greater detail, and suggested a specific allocation of responsibility for the diagnosis and treatment of cancer in a region comprising London and the Home Counties.

A Co-operative Plan

In the absence of any indication as to the official attitude towards these proposals, and as to the probable future national organization under the Cancer Act, the Governors of the Royal Cancer Hospital, acting on the advice of their medical committee, decided to expand the internal organization of the hospital, and to proceed with its plans for collaborating with a number of other special hospitals in cancer diagnosis and treatment.

This decision was prompted partly by a desire to place the exceptional resources of the hospital for diagnosis, treatment, teaching, and research at the disposal of the patients and staffs of other hospitals, and partly by a desire to obtain a larger number of cases of the less common forms of cancer both for purposes of research and in order that current methods of treatment might be tested, developed, and improved. Negotiations were therefore opened with the following hospitals, most of which had been co-operating with the Royal Cancer Hospital in an unofficial manner for a number of years: the Brompton, the Chelsea, the Gordon, the Princess Beatrix, the Royal Free, the Royal London Ophthalmic, the Royal National Nose, Throat, and Ear, and the West End Hospital. A general procedure agreeable to all was evolved.

Outline of General Procedure

The patients referred by the co-ordinated hospitals are examined at a consultation clinic at the co-operating hospital by a team comprising a physician and/or a surgeon and a radiotherapist, often with a clinical research assistant in attendance. The main lines of treatment to be adopted are laid down, and the full resources of the whole group of hospitals are available for the patients. Surgical treatment is usually carried out at the co-operating hospital, but patients may be transferred freely from one hospital to another for surgery, radiotherapy, or chemotherapy, according to the location of the equipment indicated or to the facilities most suited for the purpose.

In order still further to promote harmony and good will certain subsidiary arrangements have been made as follows. All beds in the Royal Cancer Hospital have been pooled, and all members of the cancer team—physicians, surgeons, and radiotherapists—have equal privileges in the admission of patients. Members of the staffs of some of the special hospitals co-operating have been appointed to the staff and medical committee of the Royal Cancer Hospital. This arrangement is reciprocal. A Co-operating Hospitals Committee has been set

up under the chairmanship of Lord Horder to co-ordinate the cancer work in the group of hospitals and to advise as to its future expansion

Functions and Form of the Service

Such then, in outline, is the (Experimental) Cancer Service evolved by the Royal Cancer Hospital in accord with the general principles enunciated by the National Radium Commission. It is designed to perform a dual function. First in relation to the sufferer, by placing freely at the disposal of the staffs and patients of co-operating hospitals all resources of experience, skill and apparatus in the group. Secondly in relation to research, by furnishing the clinician and research worker with a volume of material of all types of cancer, and especially of the more uncommon types dealt with in numbers by the special hospitals. This allows of the investigation of the course of malignant disease in various stages of development and in every part of the body. Incidentally the service is also invaluable from an educative point of view in that it provides data for refresher courses and for the advanced instruction of post-graduate students.

In form the organization fulfils the essential requirements of a co-operative cancer service. It might well be taken as a pattern for remodelling some other cancer services since it provides for the examination, diagnosis, and planning of treatment of the patient by a team of experienced men, and offers to patients of the group the advantages of being treated at a well-equipped irradiation centre by experienced radiotherapists. Moreover it provides adequate samples of malignant disease for investigation and research. The number of new cases seen for diagnosis and treatment per annum by the services has already passed the 2000 mark (which approximately represents the normal incidence of cancer in a population of two millions). Further expansion is at present limited by the number of beds that can be made available.

An important feature of the service is that it has no geographical limits, but is designed to deal with all forms of cancer, including the more uncommon forms which are selected for specialized treatment at the special hospitals, whatever the origin or domicile of the patient may be.

TRANSFER OF ASLIB MICROFILM SERVICE

Since the information contained in scientific and technical periodicals is often of vital importance to research, the cutting off, in the early days of the war, of normal supplies of European journals presented grave problems. To meet these difficulties Aslib (the Association of Special Libraries and Information Bureaux), with the help of the Royal Society, the Rockefeller Foundation, and British industry, organized a microfilm service in April, 1942, to supply, in microfilm or paper enlargements, copies of scientific and technical periodicals published in Germany and countries occupied by Germany during the war years. The service was used by the British and American Governments, by more than 300 scientific institutions and research stations in Great Britain and the Empire, and, under a special agency arrangement, by several hundred institutions in the United States. The library of master negatives accumulated for the purpose contains some 14,000 separate issues of approximately 500 titles equivalent to a total of over a million copies.

The Aslib Microfilm Service also undertook, on behalf of the British Council, the supply of microfilm copies of British periodicals to China while that country was cut off from ordinary surface transport. The proportions of this scheme grew until during the last year some 170 periodicals were regularly microfilmed and six positive copies of each were flown to China. Chinese scientific and cultural organizations, with the help of 100 microfilm projectors set up in about a dozen reading centres, have been able to keep in touch with developments in the outside world.

The end of the war reduced the demand for the special functions the Aslib Microfilm Service had been set up to fulfil and it became evident that the demand for documentary reproduction as an aid to science and learning though potentially great, needed further time for development in Great Britain. A scheme for the rehabilitation of medical libraries in Europe

was then brought forward by the Royal Society of Medicine. Aslib has agreed, therefore, to the transfer of the Microfilm Service to medical uses and, by arrangement with the Royal Society of Medicine, the Aslib Microfilm Service became on Jan. 1 an integral part of the Central Medical Library Bureau of the Royal Society of Medicine. Requests for copies from existing master negatives and for copies of individual references should be addressed to Aslib, 52, Bloomsbury Street, London W.C.1.

RESEARCH IN BLOOD DISEASES

The trustees of the Lady Tata Memorial Fund invite applications for grants and scholarships for research in diseases of the blood with special reference to leukaemia, in the academic year beginning on Oct. 1, 1946. Grants of variable amount are made for research expenses or to provide scientific assistants to senior workers. Scholarships are awarded as personal remuneration; their normal value has been £400 per annum for whole time research, with proportionate adjustment for work on a part-time basis, where this is approved. The grants and scholarships are open to workers of any nationality, and in any country in which it will be possible to make payments in the coming academic year. The available information on this point, regarding particular countries outside the British Empire, will be supplied to intending applicants on request. Applications must be submitted before March 16, 1946, and the awards will be announced by the trustees in June. Further particulars and forms of application may be obtained from the Secretary of the Scientific Advisory Committee, c/o the Medical Research Council, 38, Old Queen Street, Westminster, London, S.W.1.

SHORT-SERVICE COMMISSIONS FOR SPECIALISTS

A CALL FOR VOLUNTEERS.

The Central Medical War Committee has been informed that, on the recommendation of the Medical Personnel (Priority) Committee, it has been decided that specialists and graded specialists, recruited to the medical branches of the Forces, will now be accepted for short-term employment for eighteen months if they were born before July 1, 1915. The commissions held will be known as "specialist short-service emergency commissions." They will be granted to those specialists and graded specialists (born before the above date) who are called up under the compulsory recruitment procedure and to those above military age (born before July 1, 1905) who offer their services voluntarily.

The Central Medical War Committee is instructed to carry out specialist recruitment to the extent necessary for the replacement of serving specialists who are due for release in Class A or recommended for release in Class B and who cannot be released unless substitutes are provided. The Committee has been making every effort to increase the yield of specialist recruits but with only limited success and already there are a considerable number of Service specialists whose release in Class A is being retarded. The Committee therefore appeals for offers of voluntary service, and hopes that specialists above military age who might hesitate to offer their services for an indefinite period will be prepared to accept the new short-service commissions. Officers holding these commissions will be returned to the United Kingdom before the end of their 18 months' service, and will be eligible for 28 days' leave on full pay on completion of their service.

Volunteers should communicate with their Local Medical War Committees, or, in the London area, with the Committee of Reference at B.M.A. House, Tavistock Square, W.C.1. The need is urgent, and it is hoped that there will be an immediate response to this appeal in order that serious hardship to the Service specialists due for release may be prevented.

The short-service commissions will not be granted to general duty officers, but doctors will no longer be recruited compulsorily for general duty unless they were born on or after July 1, 1915. Civil direction is now applied only to men doctors below the age of 31. Women doctors are no longer liable to direction.

APPOINTMENTS UNDER CONTROL COMMISSION FOR GERMANY

An announcement in our advertisement columns this week invites applications from medical officers of health for service under the Control Commission for Germany. These officers, who will for the present serve at H.Q. of Corps, Districts, and Provincial Detachments, will be responsible for carrying out the policy of the Commission in the supervision of the German local organizations in charge of the health of the civilian population—including the medical examination and "dusting" of returning refugees—and for the health (including hospital care) of displaced persons, for which U.N.R.R.A. teams will come under their supervision. It will be their work to build up the German health services from the chaotic state in which they were found after capitulation, and their duties will be concerned with: repair and rebuilding of hospitals; staffing and organization of hospitals; reopening of medical schools and bacteriological laboratories; reorganization of nursing services and health visiting and welfare services; reopening of maternity and child welfare clinics and tuberculosis sanatoria; immunization and vaccination; bacteriological tests of water supplies; and sewage disposal. They will advise on and direct the notification of births and deaths, the control of infectious diseases, and the supply of drugs. They will supervise the B.R.C.S. and, generally, the plans for dealing with epidemics, stores, hospital expansion, etc.

Nova et Vetera

MEMORIES OF CLIFFORD ALLBUTT

Many recollections of Sir Clifford Allbutt by his old students were given at a meeting of the Section of the History of Medicine of the Royal Society of Medicine on Nov. 7. The occasion was the fifth of a series of papers on Cambridge medical history by Sir Walter Langdon-Brown, who, in this last of the series, took Clifford Allbutt as the exemplar of the transition from 19th to 20th century medicine. Unfortunately Sir Walter's state of health did not permit him to read the paper himself, and it was read in his absence by his successor in the Regius Chair at Cambridge, Sir Lionel Whitby. One perhaps forgotten episode in Clifford Allbutt's life was his three years as a Commissioner in Lunacy, when he settled in Kensington among an artistic coterie which included G. F. Watts, Lord Leighton, Burne-Jones, and others. Next door to the Allbuts at that time lived Mrs. Russell Barrington, nicknamed the "Duchess of Kensington," who made Clifford Allbutt the hero of her novel *St. Luke of the Nineteenth Century*. It has often been stated that, at a much earlier period than this, George Eliot drew the portrait of Lydgate in *Middlemarch* from Clifford Allbutt; certainly she knew the Allbuts well.

Sir Walter Langdon-Brown recalled the inaugural lecture at Cambridge in 1892: "His handsome, dignified, well-groomed appearance made an instant appeal. Still more impressive was the substance of the lecture, blending science with the humanities, which gave me a new outlook. It was really a decisive influence in my life." Speaking of Allbutt's last years, he said that, apart from the handicap of deafness, he never, even physically, seemed to grow old until quite shortly before his death. He would refer humorously to age as "that state of mind which seems mellow wisdom to its owner, but appears to the younger generation as senile obstinacy." Sir Walter thought it would be a misfortune for Allbutt's memory if Orpen's portrait of him in the Fitzwilliam Museum should come to be regarded as an authentic likeness, for it was almost a caricature. When taxed with this Orpen said, "Well, to tell the truth, I was not interested in the old man"—a criticism of the artist rather than of the subject. It was extraordinary, said Sir Walter Langdon-Brown, how Allbutt managed to keep up with the doings of his old alumni. Any one of them who did a good piece of work would probably receive a letter in a curious script which, when deciphered, would prove to be a charmingly phrased note of appreciation from the Regius Professor. His fastidious taste in literature made him a stern critic of his own writings. The fact that they read so smoothly

and pleasantly was because he always wrote three drafts before sending them to the printer.

Allbutt's philosophical attitude was exemplified in a letter written to Sir Walter not very long before his death in which he said that he knew rather than felt that he was approaching the end of a long life. The last time they dined together Allbutt said, "It isn't dying I mind; what I fear is incapacity"—a disaster which he was spared. He was a deeply religious man and preached not infrequently in St. Edward's, the little church in the market-place at Cambridge. He was greatly attracted towards the Society of Friends, but he was accustomed to say, "How can I leave the Church [of England] in which I was born, baptized, and married, with which all my life has been inextricably bound up—tendrils everywhere?"

After the paper other members of the Section spoke of their own contacts with Clifford Allbutt. Dr. Ashworth Underwood mentioned his wonderful library, and deplored the fact that his books had not been brought together as a great memorial. Dr. Alison Glover, who said that he believed he was the oldest student of Allbutt present, recalled his constant kindness, his advice when he presented his M.B. thesis—"My boy, read Macaulay"—and his appearance—the aquiline nose, the piercing eyes, and the great dignity. This impression was carried further by Dr. R. J. V. Pulvertaft, who likened Allbutt coming into the classroom to Moses coming down from the mount. Another who claimed the honour of being a student of Allbutt, though too old actually to learn from him at Cambridge, was Dr. Parkes Weber; he was only in time to read his M.D. thesis before him. Comparing Allbutt with Osler, he found the latter a little more stimulating, though Allbutt took just the same kind of interest. One of the points to be stressed was his extreme kindness, even when he criticized.

Sir Henry Tidy said that it was almost indecent for an Oxford man to break into these proceedings, but he actually met Allbutt before he went to the Regius Chair at Cambridge. He was then a comparatively young man, though, with his beard, he appeared to be of patriarchal age to a young boy; but always he had the extraordinary ability of making himself seem to be of the same age and standing as the person with whom he was talking. The pomposity of age was never his, and he combined dignity with an extraordinary feeling of friendship. Dr. H. P. Bayon recalled an occasion when, reading a paper, he described typhoid as a "clinical entity" and elicited the remark from Allbutt, "My dear fellow, never mention anything as an entity which you cannot put on a plate on a table." A letter written by Allbutt in 1922 was produced by Dr. H. J. Norman, in which Allbutt said of his contemporary Maudsley, "I could never read his books for long nor often, for what we may, for brevity, call the spiritual side of his mind's eye was almost quite blind, so that his books are depressing and arid." He also wrote of Maudsley, "Though a most successful man, I think he said that old age was the most dismal part of life. . . . Most of us old chaps who keep fairly well find it the happiest time." The train of reminiscence was brought to an end by Sir Lionel Whitby, who knew Sir Clifford Allbutt in his later years: "His manner of teaching was that of stimulating the student to observe for himself, not the method of direct demonstration. . . . He would ask you to describe exactly what you found, and that, I have always felt, is the true way in which to teach students medicine."

The July issue of the *Bulletin of the Medical Library Association* contains a useful bibliography, compiled by Dr. J. M. Schneek, on bibliotherapy and hospital libraries (350 items).

In honour of the four-hundredth anniversary of Conrad Gesner's bibliography, *Bibliotheca Universalis*, the New York Academy of Medicine library has held an exhibition of books on medical bibliography to the end of the eighteenth century.

The Museum Book Store Ltd., 45, Museum Street, London, W.C.1, have acquired the library of the late Prof. Hans Sachs, the eminent serologist, and would send particulars to anyone interested in purchasing. The collection includes long runs of *Centralblatt für Bakteriologie*, *Zeitschrift für Immunologie*, etc., numerous books, and a collection of offprints and "separata" from periodical and serial publications which total over ten thousand items in 119 labelled boxes.

Reports of Societies

PUERPERAL BACTERAEMIA AND SEPTICAEMIA

A discussion on this subject took place at the meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on Jan 18, Prof F J BROWNE presiding.

Mr. JAMES WYATT introduced the two openers whose contributions were based on work in the puerperal unit at the North-Western (L.C.C.) Hospital Hampstead where cases of puerperal infection have been concentrated since 1927. In 1936 a laboratory was established in the grounds of the hospital with Dr Cruickshank in charge and since that time every case has had a full investigation.

Bacteriological and Clinical Pictures

Dr R CRUICKSHANK said that bacteraemia had more than one definition. It might mean a transient invasion of the blood stream by bacteria from a local focus. But the type of bacteraemia into which most of his cases fell was a more persistent condition, which it was often difficult to distinguish from septicaemia. In many cases of puerperal infection there was a local focus from which a seeping or spilling took place into the blood stream and the resulting bacteraemia was of a more persistent type than was ordinarily found. His material was derived from over 2,000 cases in all of which blood cultures had been taken, usually on the morning after admission to the hospital. He divided them into post-abortion and post-partum pyrexia, 760 patients in the course of eight years had shown the former condition and 1,265 the latter. The number of cases of septicaemia relative to those of bacteraemia was much heavier in the post-abortion group. The first important factor was the age of the patient. A considerably higher incidence of septicaemia was shown in the age groups over 35. There appeared to be certain factors which predisposed to blood stream infections by organisms present in the genital tract. In the post-abortion group it did not seem likely that it was trauma to the genital tract which was the principal cause, the important factor was retained products. In the post-partum series a high incidence in primiparae indicated that trauma was important in the blood stream infection. There had been a decided fall in incidence since the introduction of sulphonamide treatment except in septicaemias in the post-abortion group. A fairly high frequency of infection with *Staph aureus* was demonstrated in the post-partum series, *B. coli* exhibited little tendency to produce septicaemia.

Dr A M RAMSAY said that bacteraemia was predominantly a feature of focus borne infection. Cases which had no clinical or bacteriological evidence of infection constantly showed what he had termed a reactionary pyrexia, he did not know the reason for it. The problem arose as to whether retained products should be left *in situ* on the ground that by undue interference infection would be spread. In the puerperal unit a careful *in media* had been adopted in that respect and the products were removed gently if it was possible to do so. Another point was the necessity for some objective criteria by which the degree of infection might be assessed before chemotherapy was instituted if a positive blood culture were found and chemotherapy then instituted one felt that one was cutting short an incipient septicaemia which might not be the case. The mortality rate from puerperal septicaemia was definitely falling before the era of the sulphonamides.

A Question of Nomenclature

Mr G F GIBBERD read into the openers' remarks a plea that blood stream infections should be classified into three groups: (1) a group which could be ascribed to an individual inoculation, (2) a group which gave the clinical picture of bacteraemia based on the fact that there were very few organisms in the blood that they were non-persistent and that the patient did not feel very ill, and (3) septicaemias in which many organisms appeared in the blood for a good many days and the patient

felt very ill. He believed it was a grave mistake to put patients into this grouping. Everyone would agree as to the first group. It could not be fair to regard a patient as seriously ill because she had organisms in her blood after a deliberate trauma. It was an advantage to separate the bacteraemia following a non-repeated trauma. But all the other cases should be put into one group and if there was objection to the word "septicaemia" some other term should be found. Septicaemia implied to the lay mind a very serious illness. Prof Ryle was so much upset on being called to see people who relatives thought them to be dying because they were said to have septicaemia that he declared that a distinction must be made between septicaemia and a condition in which bacteria were in the blood. Bacteraemia said Prof Ryle was not a clinical diagnosis but a laboratory finding, but he was immediately in difficulty because he had to invent a clinical disease in the case of people who had bacteria in the blood and were not very ill, and he called it "bacteraemic fever," which did not clear the issue at all. The speaker could not accept the view that those who were not ill were essentially different from—though they were more lucky than—those who were very ill. Dr Cruickshank had said that he regarded bacteraemia as a spilling over into the blood stream from a focus of infection but so was septicaemia. If the name must be changed let it give place to 'blood stream infections' arbitrarily divided into mild and severe. They should not bear the names of two different diseases.

Dr A J WRIGLEY said that they were asked as clinicians to say what they would do in the case of a woman who had had an abortion and was running a temperature. He had tried to recall a single case of a patient who was ill and who following the gentle removal of some retained products had become very ill and died. He could not do so. Dead tissue in the uterus would inevitably give a culture medium for anaerobes but no great trouble or illness need be expected unless the local resistance of the patient had been greatly lowered by tissue damage or loss of blood. The *Wichitana* organisms often appeared if looked for and one anticipated a very serious illness yet this did not develop.

Mr ALECK BOURNE agreed with Mr Gibberd that it was a dangerous thing to suggest that there was a difference between bacteraemia and septicaemia. A bacterial count might rise from 20 to 2,000 in 24 hours and he could not classify a case as bacteraemia if he had no means of knowing whether, on the following day, it might not show a virulent septicaemia. Those who had the management of these cases must be allowed to treat them according to clinical indications. Dr J V O'SULLIVAN spoke to the same effect. Dr CARLILE said that his work was in the depth of the country, where laboratory report arrived after the battle was over. It was of great importance to decide which were trivial temperatures and which were those demanding serious attention. For many years he had had two criteria which so far had never failed him. The first was headache and the second was a subjective sense of temperature instability, the patient feeling intermittently hot and cold. When he found these conditions with a rise in temperature he took drastic measures.

Dr MALCOLM DONALDSON said that he was taught as a student that septicaemia was a condition in which the organisms increased and multiplied actually in the blood though whether it was possible to discover that they did so he did not know. Prof F J BROWNE said that he had never made a distinction between puerperal bacteraemia and puerperal septicaemia. They were the same thing, and he thought the openers had introduced an unnecessary complication. The discussion was continued by Dr J M ALSTON, Dr MARY KENY, Dr FLEW, Dr J S McVINE, and others.

Openers' Replies

Mr JAMES WYATT said that he agreed with Mr Gibberd and Mr Bourne that the clinical picture was the important thing, and it was interesting that there did occur from time to time a temporary growth of organisms. They were still in doubt as to whether this temporary invasion was due to the virulence of the organisms or the lowered resistance of the patient, no doubt that would one day be determined. His own experience

was that the two factors of major importance in dealing with puerperal cases were the pulse rate—which was more important than the temperature chart—and a characteristic dry and furred tongue.

Dr. CRUICKSHANK said that he was quite unrepentant. He still thought "persistent bacteraemia" a good term, and he believed that the followers of the most conservative branch of medicine—the surgeons—were on his side. Some would suggest "mild blood stream infection," but why use four words instead of two? This term "bacteraemia" did describe the type of the infection. So long as the infection remained local, spilling over into the blood stream, it was a bacteraemia, but as soon as there was a generalized instead of a local infection (he did not think the organisms multiplied in the blood stream itself, but they did multiply in many foci of the body) it became a septicaemia. Septicaemia was a condition in which there was a progressive increase in the number of organisms in the blood stream.

Dr. RAMSAY said that there was no doubt that the diagnosis of septicaemia was essentially a clinical one. They had as a unit been doing routine blood culture on all cases since 1936, and therefore they had findings as regards blood cultures which anyone not doing such routine work would not get, and they could not honestly include all these cases as septicaemias. The qualitative count was a rough guide.

THE PHILOSOPHY OF MEDICINE

An introductory lecture entitled "The Search for a Philosophy of Medicine" was delivered on Jan. 22 in the Pollock Memorial Hall, Edinburgh, by Dr. DOUGLAS GUTHRIE, Lecturer on History of Medicine, University of Edinburgh. The chair was occupied by Principal Sir John Fraser.

Dr. Guthrie referred to the age-long quest for a theory or basis of medical knowledge and to the sects and "systems" which had been evolved from time to time in answer to this inquiry. The physicians of the Hippocratic school were the first to recognize disease as a natural phenomenon, neither sacred nor magical, and since their day medicine had been a battleground for all manner of theorists who were unwilling to follow the simple Hippocratic rules. Throughout a long career medicine had stood midway between science and philosophy and had been deeply influenced by current views in both those departments of knowledge. The philosophy of Descartes led to the appearance of a mechanical school of medicine, the iatrophysicists and iatro-chemists of the seventeenth century. It was Sydenham who showed a better way, by insisting that medicine could never become entirely scientific. There would always be an "art" of medicine, that elusive and unknowable factor which must be simply accepted.

The two great trends of present-day medicine, socialization and specialization, had added considerably to the complexity of the problem. Practice tended to outweigh theory, and the cultural basis of medicine was apt to be lost in a mass of technical detail. There was great need for a restatement of fundamental truths; in other words, for a philosophical approach to the study of medicine. The best, and indeed the only, means of finding such a basis was through a study of the past—the difficulties of the pioneers, the rise and progress of medicine from the earliest times to the present day.

HOSPITAL PHARMACY

At a meeting of the Society of Medical Superintendents (London and Home Counties Branch) Mr. R. H. HENRIKSEN, President of the Guild of Public Pharmacists, spoke on "Hospital Pharmacy." He recalled the events leading up to the formation of the Pharmaceutical Society in 1841 and the granting of its Royal Charter in 1843, and gave a brief survey of the statutory duties imposed on the Society by the Pharmacy Acts of 1852, 1868, and 1898, and the Pharmacy and Poisons Act, 1933. The Society maintains two Registers—one of chemists and druggists, and the other of pharmaceutical chemists, admission to each being confined to those who have passed the appropriate examinations and complied with other conditions. Only persons whose names appear in one of these Registers may use any of the following titles: Member of the Pharmaceutical

Society, pharmacist, dispensing chemist, dispensing druggist, chemist and druggist, druggist, or (if used in connexion with a retail business) chemist. The titles pharmaceutical chemist and pharmacist are reserved for use by those whose names appear in the Register of Pharmaceutical Chemists.

Mr. Henriksen next considered the functions of the Pharmaceutical Society, with particular reference to its research laboratories and college, which is a School of the University of London, and described the training of the pharmacist. Discussing the proper functions of the hospital pharmacist, he pointed out that many hospitals did not in fact utilize fully the services of their pharmacists, owing to lack of adequate accommodation, equipment, or staff. Since every advance in medicine meant more work for the pharmacist it would be essential, to ensure a satisfactory hospital pharmaceutical service, not merely to restore staff and equipment to pre-war levels but to reach the much higher standards now necessary, and attention must be given to the serious problem of bringing into hospital service an adequate number of the highly trained pharmacists who were showing an increasing tendency to take up other fields of work because of the better salaries, conditions of work, and prospects offered in other branches of the profession.

The chief points in the report on the development of the tuberculosis services which was presented to a recent meeting of the Joint Tuberculosis Council were: (1) tuberculosis work should be organized regionally, joint boards having executive powers being set up for the purpose; (2) the areas served by the boards should be approximately the same size as the new regions under the projected National Health Service, but local administrative units should serve a population of about 250,000; (3) the environmental and preventive aspects of tuberculosis work should not be divorced from the clinical; (4) the senior clinical tuberculosis officer for each region should have right of access to the joint board; (5) there should be opportunities for promotion which would provide incentive for the best clinicians to devote themselves to the work; (6) the clinician in tuberculosis should be recognized as a specialist and accorded appropriate rank and pay. At the same meeting the council approved the final draft of a memorandum of advice on Mantoux conversion of hospital and sanatorium staffs. Copies of this and of the Development Committee's report may be had from the hon. secretary of the Council, Dr. Norman England, 1, Becket Street, Oxford. Dr. D. P. Sutherland, Manchester, was nominated as next year's chairman.

A new medical society has recently been formed in Buckinghamshire called the Mid-Bucks Medical Society. The first meeting of this society took the form of an inaugural dinner at the *Bull's Head*, Aylesbury, at which some 60 founder members attended. An address was given on the purposes and functions of medical societies by the President, Major-Gen. Sir Heneage Ogilvie. The chairman of the Society is Dr. J. W. Craig, of High Wycombe, and the treasurer and secretary Mr. W. D. Lovelock-Jones, of Amersham.

U.N.R.R.A.'s DENTAL WORK

U.N.R.R.A.'s dental consultant in London is Lieut.-Col. G. A. Nevitt, Public Health Service, U.S.A. With his assistance the Health Division has arranged for the following dental services to be provided. All displaced persons either in refugee camps in the Mediterranean area (Palestine, Egypt, and Italy) or in displaced persons camps in Germany and Austria who desire dental treatment may obtain extraction, insertion of permanent fillings, treatment of diseases of the mouth, and replacement of missing teeth where such replacement is essential for the maintenance of health and efficient mastication. The dental service for displaced persons in Palestine and Egypt has been in operation for over two years. Dental care for about a million displaced persons in Germany is now one of U.N.R.R.A.'s problems. A programme for these people has been in operation for more than six months, and there are six U.N.R.R.A. dental administrators (dentists with public health experience) in Germany, assisted by displaced persons with dental experience, and where these are not available German personnel is employed. Dental aid is being given by U.N.R.R.A. in Greece; 100 complete dental units and supplies have been dispatched, and more will be sent later. Six dental scholarships have been arranged for Greek dentists for post-graduate work in America and Great Britain, and it is hoped to provide similar services in other places where U.N.R.R.A. works. Lieut.-Col. Nevitt is preparing to go to Poland on a combined lecture tour and survey to advise on the dental situation and the necessary programme for dental work.

Cardiac Massage

SIR—Mr Hamilton Bailey (Jan 5 p 29) does well to insist on the vital importance of speed in commencing the treatment that really matters in cases of cardiac failure during operation and on the futility and danger of wasting time on artificial respiration. When however, he couples the injection of adrenaline with artificial respiration as merely another means of wasting precious time I must venture to join issue with him. I consider it a positive cancer. We take infinite trouble when injecting a local anesthetic in a patient with toxic goitre to avoid injecting the least quantity of adrenaline into a vein for fear of causing the heart to stop in ventricular fibrillation, and yet we are urged by some authorities to inject heroic quantities of this highly dangerous drug into a heart that has already stopped. In my view any success that may have attended such treatment is due to the mechanical prick of the needle stimulating the ventricular wall combined with a failure to inject any adrenaline into the cavity of the ventricle. Believing this, I have long abandoned the use of adrenaline as positively dangerous but I regard the insertion of a needle into the wall of the ventricle as the quickest method of inducing the arrested heart to resume its beats. The needle need not be a hypodermic one, a long fine skin needle is equally effective. It can be thrust into the ventricle through the chest wall, or through the diaphragm if the abdomen is already opened, without more than a few seconds' delay. If the puncture fails cardiac massage through the diaphragm can be started at once, but I have found more than once that the prick has been enough to start the heart beating again without any need for massage. Where as in thyroid operations one has no intention of opening the abdomen this is an obvious advantage—I am, etc.,

Manchester

JOHN MORLEY

Paralytic Ileus

SIR—As one who has been keenly interested in the prevention and cure of post-operative complications during the past fifteen years may I make some comments on paralytic ileus, which has recently been under consideration. It is indeed encouraging to see that general interest has advanced beyond treatment to the preventive stage. Mr J T Chesterman and Dr W J Sheehan are to be congratulated on their paper (Oct 20, 1945 p 528) which has reawakened interest in this most important condition. The periodic exchange of views on these old but consistently recurring problems does nothing but good in helping to clarify our ideas.

I cannot help feeling that while their practice of using morphine as a preventive of paralytic ileus is sound their explanation of its action (Mr J T Chesterman Nov 24 p 740) is not the whole story, for they and Prof J H Burn (Nov 3, p 622, Dec 8, p 817) are almost exclusively preoccupied with its local action on the bowel. Let us first of all consider some of the causal factors in paralytic ileus. The predisposing factor is the nervous patient, the highly strung, imaginative, sensitive patient, the frightened patient, the patient whose increased sensitivity is not combined with and tempered by an equal increase in courage. The dim-witted fowl or bovine country clod never develops ileus, not having enough imagination to realize what is happening or to be afraid. Nor does the highly intelligent and sensitive but highly courageous individual usually, though he might be very frightened. The exciting causes are pain especially if severe and prolonged without relief or remission, infection, especially if intraperitoneal and in the mid- or upper abdomen, dehydration by vomiting or sweating or deprivation; physical exhaustion and starvation, exposure to the elements, and, most important poor anaesthesia and bad surgery. The latter group includes rough handling of tissues, especially viscera, extensive cooling and drying of peritoneal surfaces, severe loss of blood before during or after operation. The precipitating cause is the failure to prevent slight and early post-operative distension from developing into frank paralytic ileus.

While Mr Chesterman and Prof Burn have quoted conflicting views on the local action of morphine on the bowel, I feel that they have both almost completely ignored the central part of effect of this most valuable drug. Surely as nervousness and fear fatigue and pain are such important factors in the production of ileus, the liberal administration of morphine will be most beneficial in its prevention and cure. In planned operations it is essential to ensure sound sleep and alleviation of apprehension prior to operation. Apart from fear there is little else we can do about the predisposing factors. As regards the existing factors, pain must be controlled as far as possible before, during and after operation. It is very wrong for the doctor or nurse to withhold morphine for it is needed on the specious grounds of the risk of drug addiction. This will not develop with the generous use of morphine for the first few days following operation. Once the surgeon has done his best operatively, sleep and freedom from pain are of inestimable value in promoting speedy recovery. The other exciting factors must be dealt with so far as possible before operation, and perhaps during and afterwards also. Good anaesthesia with careful and gentle handling of tissues are of supreme importance. As regards the precipitating cause, eternal vigilance and prompt action are the answer here. To delay until the ileus is well established is to court disaster. While morphine may have some local action in preventing and overcoming ileus, I have used it more for its central effect in association with physostigmine, which is advocated by Prof Burn. But I have found synthetic physostigmine (prostigmin) more effective, and during the past ten years have had only one failure with the scheme of treatment I described earlier on (*Lancet*, March, 1940). This combines physiological stimulation with the "morphine and rest" scheme. My system is to inject prostigmin 1 ccm (0.5 mg) subcutaneously repeat it in half an hour and follow with an enema capon's in another half-hour. The prostigmin sensitizes the bowel and the enema pulls the trigger with a resultant expulsion of flatus fit to blow the house down. Then morphine (or omnopon) is given to ensure a sound sleep for several hours after which the patient looks and feels quite a different being. As Prof Burn and Mr Chesterman mention prostigmin may produce nausea and vomiting even abdominal colic, and sometimes some collapse with fall in blood pressure. For the nausea and colic Prof Burn advocates a smaller dose. I have tried giving 0.5 ccm (0.25 mg) doses of prostigmin at quarter hourly intervals in debilitated patients, thus, avoiding the untoward secondary effects, but usually with less success in overcoming the ileus. Anyhow these unpleasant reactions are short lived and seldom severe and of only minor importance compared to the benefit gained as regards the ileus. To prevent collapse in ill patients coramine or anacardone (mefenhamidum B.P.) is administered when necessary. The prognostic sign relied upon beforehand is not so much the degree of distension or size of the abdomen as the tension of the distended abdomen—i.e. the more tense the more serious and the more difficult to treat successfully. Also the success of treatment is caused not so much by the amount of faeces and flatus passed as by the increased softness of the abdomen afterwards.

It may be as Mr Chesterman says that prostigmin used thus does not produce "any true peristalsis" or "lasting increase of tone" though it temporarily causes "marked intestinal contractions" for it is sometimes found necessary to repeat the course of treatment daily, or perhaps more than once each day for several days. (After that enemata alone usually suffice.) And perhaps he will attribute the success that has invariably followed (except for one case) to the associated use of morphine, in spite of the evidence quoted by Prof Burn. But I know that my scheme has worked successfully during the past ten years. My use of morphine is in agreement with Mr J J Robb (Dec 29 p 938) who says "My own belief in morphine not as a specific but as an almost essential adjunct in the treatment of ileus, remains unshaken."

Perhaps brief reference might be made to the other forms of treatment still described in many textbooks though archaic and mostly quite ineffectual in true paralytic ileus. Associated aperients and/or enemata are usually quite useless. Passage of a flatus tube, still the delight of some sisters and nurses, cannot do more than deflate the rectum and lower pelvic colon at most, and carries grave risks of perforation of the distended

and thinned bowel wall, the acute kinking of which prevents its further passage. Repeated fractional subcutaneous injections of pituitrin and/or eserine (physostigmine) have been equally inefficient, in my experience, as prophylactic or cure. Pituitrin by intravenous injection produces violent contractions of the bowel by direct stimulation of plain muscle, but also most severe and dangerous collapse of the ill patient. Fortunately ileostomy is seldom done nowadays, for rarely can more than a foot or two of bowel be deflated, and the struggle to close the abdomen over the still-distended gut is most shock-producing to the patient. Among more recent methods of treatment, gastric suction through the Miller-Abbott tube has its supporters. But I feel that it deals with only one manifestation of the paralytic ileus—the regurgitation of small-bowel contents to the stomach, and vomiting. Admittedly this fluid is most toxic to the patient if absorbed, and its removal is both a boon and a blessing. Furthermore, with gastric suction going on, fluid can be taken by mouth to help overcome the tendency to dehydration and to act as a gastric lavage. Also, and most important, such gastric suction saves the patient the distress and fatigue of vomiting. And one must replace the fluid and chloride by intravenous saline administration to prevent dehydration and alkalosis. But in true paralytic ileus I do not believe that peristalsis will begin spontaneously after the stomach has been emptied, and so carry the tube down to the jejunum and ileum.

So one has still to deal with the functional intestinal obstruction, which, in my experience, is best done by the combination of prostigmin, an enema, and morphine.—I am, etc.,

Mount Vernon Hospital,
Northwood.

ALAN SHORTER.

Transverse Abdominal Incisions

SIR,—In the *Journal* of Jan. 12 (p. 63) I am reported to have stated at the meeting of the Section of Surgery of the Royal Society of Medicine on Jan. 2 that "the transverse incision had the disadvantages that it took a long time to make . . . and left a weak abdominal wall, so that hernia was prone to arise afterwards." I should be grateful if you would permit me to contradict this statement, as it is contrary to my experience and my teaching concerning this valuable type of abdominal incision.

There is obviously no standard method of opening the abdomen, and the choice of incision must necessarily depend upon many factors, such as the organ to be investigated, whether the disease is acute or chronic, whether speed is essential or not, the age and build of the patient, the accuracy of the diagnosis, the presence or absence of scars or herniae of previous operations, and so forth. In my opinion vertical incisions would appear to be indicated in the abdominal surgery of infancy, when the diagnosis of the case is uncertain, where for one reason or another speed is imperative, and for acute perforations and peritonitis. Transverse or oblique incisions are, however, to be preferred for operations upon the gall-bladder and bile ducts, pancreas, spleen, and colon, for recto-sigmoid resections, for minor pelvic operations, for appendicectomies, and for such procedures as gastrojejunostomy and partial gastrectomy.

Transverse incisions are of two distinct types: (1) muscle-dividing, such as Maylard (1907), and (2) muscle-retracting, such as Pfannenstiel (1900). Transverse incisions have the following advantages when compared with vertical incisions: (1) The scars are less visible, as they are made in Langer fissure lines; (2) exposure and drainage (when required) are both better, and less retraction is necessary; (3) closure of the wound with interrupted silk sutures is easier and more secure; (4) chest complications are rare; owing to the comparative absence of pain with such wounds the patients are not afraid of cough and are able to get out of bed a day or two after a major operation; (5) ventral hernia is seldom encountered.

It is nevertheless true that transverse and oblique incisions through the abdominal wall take longer to make and to close, and that bleeding is more profuse and troublesome than is the case with vertical incisions. There is, however, no truth in the statement that sectioning one or both rectus muscles is followed by some anatomical or physiological impairment of the abdominal musculature, as I have been able to satisfy myself that the muscles when healed simply present an extratendinous intersection without any functional disablement.

The criticism that should infection follow the use of transverse or oblique incision such complications as dehiscence of the wound, eversion, and ventral hernia are relatively common events is certainly not substantiated by a careful follow-up of my own cases or by a study of the published figures. V. L. Rees and F. A. Collier (*Arch. Surg.*, Chicago, 1943, 47, 136) in 225 consecutive epigastric incisions had only one case of herniation and no case of dehiscence. A. O. Singleton (*Proc. Inter-State post-grad. med. Ass., N. Amer.*, 1944, p. 101), in his review of 9,000 consecutive abdominal operations, found that in the first group of 3,147 cases in which transverse incisions were employed there was only one case of wound disruption (0.031%) and 29 herniae (0.92%); whereas in the second, of nearly 6,000 cases, in which vertical incisions were used there were 60 wound disruptions (1.0%) and 131 post-operative herniae (2.2%).

During recent years I have employed Maylard's epigastric rectus-dividing incision (*British Medical Journal*, 1907, 2, 895), making the skin incision somewhat crescent-shaped with convexity upwards, in a large number of operations upon the stomach, duodenum, and pancreas, with the most gratifying results, and I have yet to see a case of functional impairment of the rectus muscles or of ventral hernia following the use of this valuable incision.—I am, etc.,

London, W.1.

RODNEY MAINGOT.

Post-haemorrhagic Blindness

SIR,—Sir Adolphe Abrahams's views (Jan. 12, p. 65) referring to Dr. James Black's interesting article on blindness after haematemeses coincides with personal experience on this subject. Having had occasion to consult the literature for purposes of publications to which Dr. Black so continually referred one must admit that it was not very illuminating, especially from the pathological point of view. Although many theories have been advanced—toxaemia, anoxaemia, visceral reflex action, etc.—as to the considered cause of this phenomenon, could not its production be related in some way to associated vascular degenerative change?

I do not know what the average age incidence of all recorded cases is, but it seems an unlikely development in younger people suffering from haemorrhage of any kind. No cases were recorded in the 1914-18 war (Macrae, A., *Clin. J.*, 1928, 57, 37), and Sir A. Abrahams has drawn attention to the fact that examples have not been forthcoming from military surgeons. The meridian of life or after is probably the era when this rare complication manifests itself. Dr. Black's case was that of a man aged 53, Sir A. Abrahams's were both middle-aged women, while mine was in a man of 55. One therefore wonders whether or not some simple explanation, such as loss of elasticity of the retinal vessels in association with their sudden emptying and sticking together of their walls, could not play a major part in this unusual complication.

I should like to endorse Dr. Black's final commendation as to the adoption of routine inspection of the fundi in order that all possible steps may be taken to overcome, if possible, such a tragic calamity.—I am, etc.,

Edinburgh.

C. KELMAN ROBERTSON.

SIR,—Dr. James Black's case of blindness following haematemeses (Dec. 29, p. 920) gives an interesting record of this rare event. Terson, in 1922, reviewed 250 published cases. A true perspective of the rarity of this condition was clearly shown to me when I searched through the records of the Royal Eye Hospital, London, in 1936. I was then collecting cases of sudden blindness due to the occlusion of the central artery of the retina and its branches. The records of all patients who attended at the hospital for six years (1931-6) were examined and only one case was found of unilateral blindness following a haematemeses. During the same six-year period 54 cases of occlusion of the central artery of the retina and its branches were seen at the hospital, and 205 patients who were suffering from thrombosis of the central retinal vein and its tributaries. The hospital attends, on the average, to 30,000 new patients a year. This investigation of hospital records demonstrated that only one case of post-haemorrhagic blindness was seen at an eye hospital among over 150,000 new patients. Most observers now agree that marked constriction (narrowing of the retinal arteries) is the most prominent feature of the ophthalmoscopic

picture of this disease when seen soon after the attack of sudden blindness.

Pallor of the retina, small retinal haemorrhages, and occasional retinal oedema and papilloedema are other inconstant features. In all cases optic atrophy with very narrow retinal arteries is the final late result. This ophthalmoscopic picture is so similar to the one seen in cases of occlusion of the central artery of the retina due to thrombosis or embolism of the retinal arteries that one is led to conclude that sudden spasm of the retinal artery followed by thrombosis is probably the most common cause of post-haemorrhagic blindness. In the treatment of post-haemorrhagic blindness most ophthalmologists assume that the central artery has suffered from a sudden occlusion, and the measures adopted are (1) to raise the general blood pressure and (2) to lower the intraocular pressure of the eye with massage of the eye, miotics, and paracentesis of the eye.

Subconjunctival injections of acetylcholine might also help to relieve the angiospastic condition of the retinal circulation.—I am, etc.,

London W1

SIR.—On Nov. 29, 1944, a man aged 54 years was fastening the gates and doors of the foundry in which he was employed as night watchman. He tripped over a plank and fell, injuring his left leg. There was a fracture of the left tibia at the lower third. This was treated. On Jan. 29, 1945, while still in hospital, he had a severe haematemesis for two days and melæna for several days. He noticed his sight failing. By Feb. 13 he was completely blind. I examined him on Feb. 17 and found that he had double optic atrophy. I was asked by his employers' insurance company to report on his case as he was starting a claim against his employers maintaining that the blindness was the result of the accident to his leg. He was admitted to the Royal Victoria Eye and Ear Hospital, Dublin, for the purpose of investigation under my care.

His Wassermann reaction was negative; x-ray examination of skull revealed no intracranial lesion and the general contour of the skull was normal. The radiological findings as regards the gastro-intestinal tract indicated almost complete stenosis of the pylorus. The general appearance according to the radiologist was typical of a malignant lesion. During the week he spent in this hospital there was frequent haematemesis. He died a few days later.

The medico-legal aspect of this case is interesting. One is left wondering whether the optic atrophy had been present for some time as a result of secondaries in the brain and whether the loss of blood was the final decisive factor in producing blindness in an already defective vision.—I am, etc.,

Dublin

HARRIS TOWNIN.

Homosexuality

SIR.—Public opinion, or at least that part of it which makes any pretence of serious thinking, has been disquietened by a recent case in which a scoutmaster was sentenced to fourteen years' penal servitude for immoral conduct with boys. Previous sentences of three years and six years had also been passed upon the same man, who is now 46, so that at the end of his full term, at the age of 60, he will have served no less than twenty-three years in gaol.

The popular horror aroused by the nature of the offence is such as to overshadow certain other aspects of this unhappy case, which, in an altogether different sense, are disturbing. It is now generally conceded that the majority of cases of homosexuality yield to treatment by psychotherapeutic measures, and the symptoms, often no less distressing to the patient himself than to society in general, if not cured can at least be alleviated to such an extent as to bring them under control. This being so, surely the responsibility lies with the medical authorities of the prisons in which the patient has already served nine years of his manhood to attempt some form of medical treatment while he was under their care. A grave sexual malady cries out for treatment just as loudly as a broken leg or acute appendicitis, and, although a prisoner during the time of his

detention surrenders the greater part of his personal liberties, he retains certain civil rights, of which the right to receive adequate and skilled medical attention is among the most important. It is this which distinguishes (or should distinguish) an English prison from a Continental camp.

The prison medical service, however, has its limitations, and among these is an ignorance of sexual abnormalities, which it shares with the great bulk of the medical profession. During the course of my own somewhat prolonged student and post-graduate days I received no clinical instruction whatever on sexual matters outside the narrow confines of midwifery and gynaecology, and even there the somatic approach completely predominated over the psychological. Contraceptives and the hygiene of marriage were never touched upon, while the sexual perversions were given scant notice in a few pages of medical jurisprudence which the student was expected to read, but upon which no lecturer was ever called upon to speak. That is how matters stood some 15 years ago, but if things have moved for the better the change has not yet been reflected in the pages of the *Journal*. I cannot claim to have read every issue as thoroughly as I might, but I do at least glance through the contents; I do not recollect seeing during the last ten years a single article, letter, clinical note, or other reference to homosexuality. This statement of course is subject to editorial correction, but the fact itself is certainly not due to editorial censorship, as the publication of this letter is itself a witness. Even in the freest of free countries the *B.M.J.* stands pre-eminent as a magnificent example of journalistic freedom; its pages are open to all who write with sincerity and obey the ordinary canons of literary decency. The long and bitter discussion on artificial insemination, which followed the publication of Kenneth Waller and Mary Barton's outstanding article last year, is proof that, in the pages of the *B.M.J.*, the ban is lifted from that most taboo of all subjects, male sexuality. The complete absence of any mention of sexual inversion in the volumes of the leading medical journal in the world, not being due to censorship, can be symptomatic only of an apathy and ignorance on the part of the profession which would be classed as abysmal were it not if anything exceeded by the untutored superstitions and perverted ideas of the public at large.

Surely it is now time to remedy this state of affairs. If the general public, together with the responsible authorities in other professions, are to be guided in this matter of homosexuality, it is without doubt to the medical profession to which they must look for the lead. It may reasonably be argued that topics such as this do not fittingly belong to the student curriculum; but they are nevertheless of first-rank importance to the general practitioner, to whom these unhappy patients often turn as the one friend who they know can be trusted. When one recalls the estimate given by Havelock Ellis that in 2% of the population, both male and female, there is some degree of sexual inversion, the magnitude and importance of the subject cannot be overlooked.

Not only is there the enormity of retributive sentences being passed upon patients who should be given all the benefits that psychology has to offer; there is also to be remembered the loss of potential mothers and fathers among those whose instincts have been diverted up a biological blind alley. But far greater even than these weighty considerations is the debt owed by humanity at large to these unfortunate inverts, in this country alone numbering several hundred thousand, who owing to causes which are quite beyond their own control, being abnormal in their endocrine make-up or unhappy in the environment of their early childhood, are deprived alike by Nature and by society of the reasonable satisfaction of instincts which are the foundation of human happiness.—I am, etc.,

Hayle, Cornwall

D. STANLEY-JONES.

Physical Therapy in Mental Disorder

SIR.—It seems to me wrong to make an absolute correlation between physical methods of treatment and such methods as electro-convulsive therapy and leucotomy. The objection to these methods is not that they are physical but that they are destructive. There is no doubt that there are many physical methods of treatment which are valuable in cases of mental illness. These two methods ought rather to be referred to as

electrical and surgical destruction of the prefrontal areas. These areas of the brain are generally acknowledged to have a close relation with the development of the higher faculties of the personality. It seems that many cases of mental illness arise just through the development of finer qualities—a higher sensitivity, a more delicate conscience, for instance. The conflict between these and the more animal tendencies produces the illness. This can then be resolved into one of two directions—either a higher synthesis is achieved and the personality can continue to live at a higher and more creative level, or the lower qualities gain the upper hand. Destruction of the physical basis of the higher faculties precludes the former solution. The personality is then thrown back to the former level, or usually somewhat lower, and this is then regarded as a cure by the inaccurate observer.

Does Dr. Jan Frank (Jan. 19, p. 104) really believe that the average mental hospital doctor is really capable of discerning genius? (And why should genius be referred to as a "creative crank"? Surely the crank is the man whose only idea of curing mental illness is by pressing the button of the E.C.T. machine.) Far too often the mental hospital doctor is below the level of many of his patients in general culture and intelligence. Even if this were not the case, history has shown too often that humanity as a whole has been incapable of recognizing genius until too late. Many people of genius have had short mental illnesses, which have sometimes been a prelude to a creative period, which could not have been anticipated before or during the illness.

Why does Dr. Frank refer to the opponents of fore-brain destruction as "pure-mind" mystics"? It is just because we acknowledge the relation between the physical brain and the mind and personality that we object to the destruction of the brain. If we truly suffered from an "obsolete metaphysical assumption of body-mind dichotomy" then we could not possibly object to the destruction of the brain, because this would be quite incapable of affecting the mind. We are just as anxious as he is for the progress of clinical psychiatry, but we believe this progress is being obstructed by the present craze for destruction.

Is psychological treatment ever really conscientiously carried out in the present-day mental hospital? I worked in a hospital for 370 patients, including an unusually high proportion of early treatable cases. The medical staff consisted of two—the superintendent and myself. The former was much too busy with administration to do much therapy. With the best will in the world I could not tackle the large number of quite suitable cases adequately, even if I had worked through the 24 hours. No wonder the electric button is popular.

Our objections to these methods are based not only on theoretical grounds but on a study of the actual results. The late R. D. Gillespie, in a statistical review of electrical treatment of schizophrenia from material collected throughout the world, showed that the percentage of spontaneous recoveries actually exceeded slightly the percentage of recoveries in cases treated by E.C.T. From personal observation I was convinced that the chances of many young people making a really sound recovery in both this and the affective type of psychosis were prejudiced by electrical treatment. We frequently have the wrong attitude to mental illness: the real illness often precedes the appearance of frank abnormalities, and these should be regarded as Nature's reaction to an abnormal way of life. If the illness is simply cut short by violent methods the patient all too often has to be admitted again after a short time, whereas if the whole process is allowed to work itself out a permanent cure may be established. Mental illnesses take a much

longer course in time than most physical illnesses, and patience is needed in both their treatment and the estimation of results. Often the results of these methods are dishonestly summarized by their advocates in journals of general medicine. If one turns to the original papers one finds such results of leucotomy as a rapid dementia, epilepsy, permanent incontinence of urine or even faeces, a previously quiet patient develops disgusting habits, etc. But much more serious is the destruction of the finer imponderable qualities of the personalities, which sometimes makes one feel when faced by these victims that the true individuality, the really human personality, is no longer there.

A serious matter which has come to my notice recently is the way in which friends and relatives of the patient who object

to these methods are treated. Often they are bullied into signing a statement that they agree to any method of treatment which the hospital staff think fit. If they object to electrical treatment they are sometimes threatened with the immediate discharge of the patient—a serious matter when the relatives are too poor to afford private treatment. It ought to be possible for relatives of a patient to obtain independent consultant advice on a patient in a public mental hospital, but this is indignantly refused by the hospital staff. Lastly, it is not true that no responsible psychiatrist recommends leucotomy before all other methods have been tried. Leucotomy as a primary measure has been openly advocated by Fleming in the *Journal of Mental Science*. The time seems to me ripe for securing the protection of patients and relatives against leucotomy by adequate medico-legal sanctions, and I shall be interested to hear from psychiatrists who would like to organize against this terrible method of treatment.—I am, etc.,

London, N.W.3.

T. H. B. GLADSTONE.

Tuberculosis in Childhood

SIR,—After Prof. Moncrieff's lecture comes Dr. W. F. Gaisford's article on primary tuberculosis in childhood (Jan. 19, p. 84), and one may expect shortly other signs of the activities of the paediatricians. On reading their association's two memoranda on tuberculosis and rickets a malicious observer might remark that the association comes out in the open only when the enemy is already in retreat. For there seems little doubt that childhood tuberculosis as a cause of death is declining fast, while rickets has long ceased to be a preoccupation of the busy doctor. Dr. Gaisford refers to the meeting of the paediatricians with the Tuberculosis Association, and, indeed, it was a valuable meeting, for it showed that the two groups had differing ideas of the disease; the phthisiologists were thinking of their scores of dead and dying adults, of their hundreds of men and women struggling through months and years to regain some degree of health and confidence. The importance attached by the paediatricians to childhood tuberculosis seemed almost dilettante.

First infection, an event almost always innocuous, "tuberculosis" whose only sign is the presence of a positive Mantoux test are hardly the causes to which ought to be devoted a great deal of time, energy, and money just now. Further, the mortality and morbidity, such as they are, from childhood tuberculosis will not yield to direct assault, but will rapidly respond to the hygienic education of the infectious adult and to the amelioration of the social circumstances of the family. In my own district of 140,000 people with a tuberculosis mortality of 61 per 100,000 there is on the average one death each year under the age of 5. It doesn't seem a great problem. One sees hundreds of children with positive tests and dozens with quite large primaries, all of them apparently well. The occasional case which is clinically ill requires rest like any other ill child. One child a year dies despite, perhaps, rest and the best of home circumstances, and such children appear to be like guinea-pigs, in whom the disease follows an inevitable course. Perhaps B.C.G. would protect them.—I am, etc.,

Chest Clinic, Edgware.

STEPHEN HALL.

SIR,—Dr. W. F. Gaisford's generally helpful paper reveals that the supposed divergence of views of the Tuberculosis Association and the British Paediatric Association is due to reliance, on the one part, on well-founded statistics and, on the other part, on "clinical experience." Dr. Gaisford's contention that those who work in children's hospitals see "scores of infants dying of tuberculous meningitis" cannot, however, be allowed to pass without some comment.

The average number of deaths from all cases of tuberculous meningitis for the whole of England and Wales (and this must surely include more than "infants") has for a number of years been fewer than 2,000 per annum. How is it, then, that individual paediatricians see "scores of infants dying from tuberculous meningitis"? Are death certificates being widely falsified throughout the country in the same way that Dr. Gaisford admits omission (intentional or otherwise) of notifications of Tb.? I find it difficult to believe. There is, I think, another explanation. Children's hospitals and the children's wards of general hospitals might reasonably be expected to admit a very

large proportion of all cases of meningitis, including tuberculous. This will give the impression to those treating them that this is a very common disease; hence the error that "clinical experience" unbacked by statistical checking gives. There are not, of course, "scores of infants" dying in every hospital in the land from tuberculous meningitis, but "clinical experience" makes it appear that it is so.

I sympathize with the views of Dr. Gaisford and other paediatricians. I myself have worked in a children's hospital and know the heartbreak of seeing children die and know that one is unable to help them. But this human feeling should never cloud one's wider judgement. The Registrar-General's figures for mortality are hard facts, and are, I contend, more reliable than "clinical experience." It is neither necessary nor helpful "to make mountains out of molehills."—I am, etc.,

Stacey, E.I.

R. M. ORPWOOD,
Tuberculosis Officer.

Control of Malaria in the Tropics

SIR.—In your leading article (Dec. 8, 1945, p. 808) on the control of malaria in the Tropics the eradication of *Anopheles gambiae* in Brazil is discussed, and Dr. George Macdonald is reported as foreseeing "similar operations in Mauritius, the Seychelles, and other places where conditions are favourable." This inclusion of the Seychelles surprises me. During a visit to Mahé in October, 1943, I was given to understand that there were no anopheline mosquitoes on the islands and that malaria did not exist. Great care was being taken to fumigate all ships and aircraft arriving at the port, and unless these arrangements have broken down I should imagine that a campaign to eliminate *A. gambiae* from the Seychelles would be rather unnecessary.—I am, etc.,

Alexandria,

R. H. TOWNSEND,
Surg. Lieut., R.N.N.R.

Amoebiasis

SIR.—In Mr. J. K. Willson-Pepper's "Impressions of Surgery in West Africa" (Dec. 8, 1945, p. 812) the following passage occurs: "... In my experience of this disease [amoebic dysentery], if ulceration does not come within the range of the proctoscope it is very unlikely to come within that of the sigmoidoscope, which probably means that it is not there at all. Provided certain elementary rules are observed, the chances of an immediate and accurate diagnosis with this simple and safe instrument are extremely high. The rules are these: (1) Don't give any form of treatment to the patient for 48 hours before examination, especially any rectal lavage. (2) Don't use a proctoscope which has been clipped in any antiseptic. . . ."

The above appears to contain certain dangerous and misleading fallacies in the approach to amoebiasis. First, that in amoebic dysentery our interest in the visible mucosa begins and ends with the discovery of ulcers. Nothing could be further from the truth, for this is to ignore the equally significant and characteristic lesions of pin-point craters and "pig-skin" appearance. Secondly, as a consequence, the use of the sigmoidoscope can be supplanted by that of the proctoscope. In a very large percentage of cases, in my experience, the only visible lesions are at 5, 6, and 6½ in. (12.5, 15.0, and 16.25 cm.) from the anal margin. Such lesions, it is true, seldom take the form of classical ulcers, but I have on several occasions seen isolated yellow-headed ulcers at 6 in. (15 cm.), the remainder of the visible mucosa appearing quite normal. The suggestion is reinforced by referring to the proctoscope as "simple and safe," the sigmoidoscope, by implication, being less simple and safe. Surely, with reasonable gentleness and care, there could be no safer instrument? Thirdly (though this is perhaps hardly a fair deduction), "Rule 2" might be taken to imply that the practice of sterilizing the proctoscope by an antiseptic is not unknown. I am sure that Mr. Willson-Pepper would be the first to agree that sterilization by thorough boiling of any rectal instrument is the only possible method when dealing with a series of potential cyst-passers.

Incidentally his practice of giving no preparation for proctoscopy is infinitely preferable to the elaborate and exhausting wash-outs, etc., which are occasionally inflicted on the patient, and in my experience will give about 80% efficient preparation. But one or two weak soap or bicarbonate enemas given three hours before the examination usually yield 100% adequate

results, obviating the annoying necessity of having to send away a percentage of patients until another day.

I feel impelled to call attention to these points, and to the imperative need for the maximum competence and knowledge to be applied to the diagnosis of amoebiasis in the United Kingdom in view of the great numbers of low-grade infections which without doubt will declare themselves amongst those members of the population who have served in Eastern theatres of war. Responsibility for detecting such cases will in most instances devolve upon the general practitioner.—I am, etc.,

Northam Command, India.

C. F. J. CROPPER,
Major, I.A.M.C.

The E.S.R. Technique

SIR.—I feel that an apology is needed for once more taking the field on this subject, but Dr. H. S. Gaskell's letter (Dec. 29, 1945, p. 940) contains an error of such magnitude that it should not be allowed to pass. Thus he says "it is obvious that the higher the column of blood the greater will be the amount of clear serum to be read off." (It is not serum, of course, but let that pass.) "If you take a column 100 yards high the normal fall will be about 4 yards, whereas if 160 mm. be taken it will be about 4 mm." I can assure Dr. Gaskell that this observation, so far from being obvious, is just positively not true, as a single practical observation will suffice to show. If Dr. Gaskell were a non-swimmer he would not drown five thousand times faster in the deepest part of the Pacific than in the deep end of the local swimming-bath, though the principle is similar. In actual point of fact a normal case will give the same result almost whatever column length is used. It is only in the faster rates that a short column produces an effect on the result through the earlier onset of "packing." Theoretically a column of infinite length is ideal, but in actual practice the Westergren length of 200 mm. is the best.

It seems to me that Dr. Gaskell's instructions make rather unnecessarily heavy weather of the task of filling the pipettes. These are only more difficult to fill than an ordinary chemical pipette because they are not "throttled" at the tip. It is, however, a very simple matter to "throttle" them against the bottom of the specimen-tube when filling them and when running the level down to the mark. No chemist would think of using a wetted finger for this purpose, and surely no reputable firm sells sedimentation tubes with jagged ends.—I am, etc.,

Howard's Heath.

J. W. SHACKLE.

Spinal Analgesia in Obstetrics

SIR.—As the author of the first two papers on the use of heavy (hyperbaric) nupercaine in obstetrics (*J. Obstet. Gynaec. Brit. Emp.*, 1942, 49, 247; 1944, 51, 324), I have read Dr. Louis Resnick's article (Nov. 24, 1945, p. 722) and the correspondence which has followed with more than usual interest. I am pleased to see that Resnick was able to confirm the conclusions I came to during my experience of 200 Caesarean sections under heavy nupercaine spinal analgesia.

There have been many criticisms of the use of spinal analgesia in obstetrics, and in my first paper I quoted freely the opinions of many against its use (H. R. Spencer, DeLee, Brindeau, Brouha, Voron, Kronig, Marshall, *et al.*), and in favour (Ashworth, Luker, Lloyd-Williams, Sebrechts, Murad and Parhad, *et al.*). Voron thought there was a special bulbar sensitivity of women in labour to the action of cocaine compounds. But, as I pointed out in both my papers, nupercaine is not a cocaine compound, and is therefore not open to this objection. This fact should be borne in mind in assessing the value of nupercaine as a spinal analgesic in pregnancy. DeLee quoted Kronig as saying that "spinal analgesia is dangerous in pregnancy and labour," but Prof. R. R. Macintosh and Dr. W. W. Mushin said that it appeared to them to be a bogey to suggest that pregnancy makes a woman peculiarly susceptible to the effects of spinal analgesia (*Lancet*, Nov. 18, 1944).

Commenting on my first paper, Greenhill (*Year Book of Obstetrics and Gynecology*, 1943), said he thought I had been lucky. Bourne and Williams (*Recent Advances in Obstetrics and Gynaecology*, 1945), referring to the same paper, agreed with Greenhill as to my luck, but added, "We are driven to conclude that Thomas has obtained his excellent . . . by the good work of his surgical and his . . . but . . ."

his method is not one which it is wise to teach." Good teamwork makes for efficiency in every field, but we have never employed a specialist anaesthetist. All the spinal analgesics have been given by myself or my assistants, and the method is so simple that no fewer than sixteen successive assistants have learned it in the past eight years. Why, then, should it be unwise to teach it?

In the *Year Book of Obstetrics and Gynecology*, 1944, commenting on my second paper and on a letter from me to the *Lancet* (Oct. 28, 1944) in which I had brought my total of Caesarean sections under heavy nupercaine spinal analgesia to 241 without a fatality from the analgesic, Greenhill said:

"This is a most creditable record for spinal analgesia. . . . Thomas insists that it is just as important to distinguish among the different drugs used for spinal anesthesia as it is among those used for inhalation anesthesia. This seems logical to me because, as Thomas says, one would hardly condemn all forms of general anesthesia because there have been deaths under chloroform. . . . The point made by Thomas about the type of anaesthetic used is important, and if Thomas is right, surely all the enthusiasts of spinal anesthesia who have had any fatalities from drugs other than heavy nupercaine owe it to their patients to use this anaesthetic and no other."

For any opinion to carry weight it should be supported by figures, preferably those from personal experience. My own experience of heavy nupercaine in obstetrics and gynaecology extends from 1938 and covers the following cases: forceps deliveries, 735; Caesarean sections, 282; gynaecological, 984; total, 2,001. Among the Caesarean sections were 42 cases of placenta praevia. Included among the gynaecological cases were 35 operations of hysterotomy and sterilization at about the third month of pregnancy, at least 15 ruptured ectopic gestations, a number of therapeutic abortions, and several cases of removal of ovarian cysts complicating pregnancy, including one which contained 22 pints (12.5 l.) of fluid. There has not been a fatality, either due to the spinal analgesic or under the analgesic from any other cause whatever.

I understand that Resnick's experience now extends to over 660 obstetric and 840 gynaecological cases without a fatality, which he will doubtless confirm shortly. It would appear, therefore, that between us we can cite over 3,500 operations under heavy nupercaine spinal analgesia without an anaesthetic fatality. May I end by quoting from a personal letter from Prof. Miles H. Phillips, who, commenting on my first article, said: "I read the paper with great interest and a complete dismissal of the bias against spinal anaesthesia which dated from earlier experiences with it."—I am, etc.,

Obstetric Service, Croydon.

RUFUS C. THOMAS.

Predisposing Factors in Carcinoma of the Cervix Uteri

SIR,—When I was a student at the Middlesex Hospital I believe I remember being taught by Mr. Carnac Rivett that carcinoma of the cervix uteri never occurred in the nulliparous woman. Other authorities at least say "hardly ever." It appears, therefore, that (1) pregnancy with its great hormonal changes or (2) the subsequent labour with its mechanical trauma is the predisposing factor, or, of course, a combination of the two.

It would be of great interest to know the exact percentage of cases of carcinoma of the cervix in women who have only had children by Caesarean section. There are now probably sufficient records for this to be ascertained. If the percentage were the same as for normal multiparae it would point to pregnancy as the predisposing cause, factor (2) being eliminated. It might then be worth trying to modify or nullify the carcinoma with suitable hormone preparations. After all, the oestrogens modify rostatic carcinoma. If the percentage were less than for ordinary multiparae, it would point to the mechanical trauma of labour as the predisposing cause, perhaps some tear leading to chronic inflammation, then followed later by malignant changes. In this case more attention to the cervix after labour would be due than is given at present.—I am, etc.,

London, N 3.

A. REDMAYNE NETTLETON.

Institutional Midwifery and the Family Doctor

SIR,—It may interest Dr. R. Guest Gornall (Jan. 19, p. 108) and others to know that institutional practice of midwifery by general practitioners has been conducted for many years at the

Woking Maternity Home. Last year this hospital was used by over 30 doctors, and is open to all practitioners in the district. It might be supposed that so many different men, working with different techniques, would introduce confusion, but in practice this is not the case, and the work is done with easy harmony between the medical men and the nursing staff. Over 1,000 babies are delivered yearly, and few hospitals can show such good results.—I am, etc.,

Woking.

L. G. HIGGINS.

Stethoscope versus X Rays

SIR,—The argument of stethoscope *versus* x rays is, indeed, a very old one. Paradoxically it goes much further back than the discovery of x rays. We heard the same argument as sailing-ship *v.* steamship, horse-drawn carriage *v.* motor-car, silent film *v.* sound film, and it might have existed quite recently as sound detector *v.* radar. In each of these examples the point was not what the sailing-ship, the horse-drawn carriage, the silent film, or the sound detector could do, but what they *could not do*. The same applies to the stethoscope. We know what it can do when used with skill, but we also know what it fails to do, in spite of the greatest skill.

Argument will never settle the case of stethoscope *v.* x rays, but a practical test would. Some years ago (I believe in 1938), sponsored by the American Trudeau Society, a committee was formed to decide this issue. They selected twelve first-class chest physicians, who examined a large number of chest cases, carefully recording the physical signs. When their records were compared with the x-ray films the result was a complete rout of the "stethoscopians." Would the enthusiastic defenders of the stethoscope care to repeat this experiment in this country? It would certainly give them the chance of eating the pudding instead of talking of its magnificent flavour.—I am, etc.,

Woodford Green, Essex.

F. KELLERMANN.

SIR,—In view of the recent correspondence, conducted not without some asperity, between the radiologists and the clinicians as to the diagnostic value and merits of their respective methods, may I bring to notice the following case, which would seem to add weight to the paramount importance of clinical observation and examination as against dependence upon x-ray findings for the purpose of establishing early diagnosis of tuberculosis of the lungs.

Miss A., aged 19, developed an apparently simple lobar pneumonia three months ago. In accordance with my experience of a series of pneumonias during the past six months, resolution of the consolidation was protracted. The acute stage was dealt with on orthodox lines together with the use of sulphadiazine. Convalescence was prolonged and unsatisfactory in that, in spite of the apparent "well-being" of the patient, the temperature refused to settle down completely. There were recurrent bouts of fever lasting a day or two, which gradually settled down to a rhythmic evening rise of temperature varying from 99° to 100° or 100.4° F. or so. Stethoscopic examination gave the usual signs of a slowly resolving lobar pneumonia, to which later became added a few transitory faint scattered rhonchi over the whole chest area. No specimen of sputum had been available throughout the illness, since there was very little cough and no attempt at expectoration. My suspicions in regard to tubercle were based upon (1) the temperature chart; (2) the facies of the patient—the somewhat transparent pallor with that typical recurrent hectic flush; (3) the faint but suspicious moist sounds elsewhere in the chest; (4) the temperament—a cheerful, sweet-tempered nature and contented resignation to the prolonged confinement to bed. I stress this last clinical observation as of some importance, since it is typical of the "phthisical" patient in all stages of the disease.

Owing to the unsatisfactory progress I had the chest x-rayed with special reference to any signs of tubercle. The films were reported upon as showing a simple resolving lobar pneumonia with no signs of tuberculous disease. The white cell count taken at the same time showed a count of 8,000. About a fortnight later, since the patient's condition remained the same, except for a transitory pleurodynia on the other side, apparently diaphragmatic, I had a further x-ray examination carried out, again stressing the question of tubercle. The report showed a progressing resolution of the pneumonic patch but again showed "no evidence of tubercle." The white cell count on this occasion was 12,000. At this juncture, and at long last, the patient produced a very small specimen of sputum, the report upon which stated the presence of a considerable number of acid-fast bacilli. A second specimen of sputum produced a week later con-

tained a large number of acid-fast organisms indistinguishable from tubercle bacilli. The diagnosis was therefore established.

The point of interest is that here was a case of early tuberculosis of the lungs which x rays had failed to demonstrate. Since the main argument in favour of mass radiography is its importance as a means of the earliest possible detection of tubercle, this particular case would seem to throw very considerable doubt upon its value or infallibility and should produce a vote of "no confidence."—I am, etc.,

Oxford.

J. FRANKLAND WEST.

Diagnostic Acumen of the G.P.

SIR.—Dr. Vincent Norman (Jan. 12, p. 67) fulminates against certain comments made by specialists concerning the work of the general practitioner. Unfortunately many of the examples he quotes recoil against him. He states: "The general practitioner, who at one time did 90% of the midwifery in this country and did it well, has been told . . . that he is a careless and poorly equipped accoucheur, a positive danger to any lying-in woman, and should on no account attend a midwifery case." If Dr. Norman Roberts does not believe this he need only attend a large maternity unit and note the emergencies admitted.

Of the three maternal deaths in this hospital last year in 1,500 deliveries one patient was admitted following a cerebral haemorrhage, her blood pressure was 190, and she had oedema. She had been seen antenatally by her own doctor, a very competent general practitioner, who had examined her with care, had noted the oedema of her legs, had failed to find albumin in her urine on repeated examinations, but had not considered that a rising blood pressure, which he had taken, was of any significance in the absence of albuminuria.

Two weeks ago a patient was admitted for repair of damage during forceps delivery at home. She was found to have the whole of the posterior cervix torn off, both lateral walls of the vagina were torn from top to bottom, and the whole of the pouch of Douglas was open. She had been delivered through an undilated cervix.

A personal friend, a one-time maternity sister, wrote recently that she was to have a baby in February and was "blown up with oedema" and that her doctor would not take her blood pressure. To-day we have had a 'phone call to say that yesterday she was seized with eclamptic fits, was rushed into hospital, and had a Caesarean section. Surely even the most stubborn must realize by now that obstetrics is a specialist art and should be practised only by those with special knowledge and experience. The individual need not be a pure specialist, as many general practitioners practise a specialty with skill as great as that of the pure specialist.—I am, etc.,

Halifax General Hospital.

H. J. DENTCH.

The Disabled Persons Register

SIR.—A new "racket" has arisen in connexion with the Disabled Persons Register which I think deserves wide publicity among the profession. It would appear that certain unscrupulous employers are trying to persuade any of their employees who have a disability of any kind to enrol on the above register, thereby attempting to avoid or minimize their responsibility for taking on to their pay-roll the legal 2% of really disabled persons. One is confronted in the surgery by a patient who has hitherto been regularly employed and is presumably a valuable employee as no question has up till now been raised over occasional or even frequent absences from work. A form is presented which the manager has told him to get filled up and signed by the doctor. So far I have refused to sign this form, but I would be glad to have the views of others.

There is a certain class of case in which there is no question of the gross and permanent disability, either surgical or medical; but there is a vast mass of cases which are borderline. Is one to certify the man who has lost a finger or the man who suffers from bronchitis every winter or the man who has frequent attacks of migraine? I could go on indefinitely listing doubtful cases, and I do not see how any hard-and-fast rules can be laid down; it seems obvious that each case must be treated on its merits.

The refusal of such certificates by a practitioner may cause much unpleasantness if employers resort to victimization of the patient, and I maintain that the decision should not be imposed

on the G.P., who has enough unpleasantness to put up with these days if he is conscientious in his certification for milk and corsets and fuel, etc.—I am, etc.,

Fitzwilliam, Pontefract.

J. S. LAURIE.

Glandular Fever and Infectious Mononucleosis

SIR.—I have read with interest Sir Henry Tidy and Dr. E. B. Morley's reply (Dec. 22, 1945, p. 896) to my letter (Nov. 22, p. 743). It is with temerity that I dare to cross swords with such acknowledged authority, nevertheless my purpose in stressing the difference between the "glandular fever" case and the "infectious mononucleosis" case was to bring out the point that the latter condition possesses certain definite characteristics, which Dr. Gerald Slot and Major F. D. Hart (Oct. 13, p. 495) had not considered. That "infectious mononucleosis" is a term in general use in the North American continent, whereas "glandular fever" is mostly used on this side of the Atlantic Ocean, is common knowledge. We have had an authoritative explanation given us as to how this arose. What is not always understood is that "infectious mononucleosis" is used in North America to describe a condition generally found among young adults and exhibiting certain clinical characteristics; whereas "glandular fever" here is used to describe that condition more commonly found in children, and varying in its clinical appearance from that condition found in the States. That it is the accepted practice in this country to use "glandular fever" and "infectious mononucleosis" synonymously when in fact different clinical appearances are being described only adds confusion and unnecessary complication.

Dr. Slot and Major Hart's case occurred in a young adult of the "infectious mononucleosis" as opposed to the "glandular fever" syndrome—this they did not make clear, neither was its significance realized. It was for this reason that I criticized them. It has long been apparent that the group of clinical conditions gathered under the umbrella of "glandular fever" comprises a larger group than that differentiated by "infectious mononucleosis," if these terms are used correctly. It is also apparent that these groups need further differentiation if clarity is to be attained.

Sir Henry Tidy and Dr. Morley state in their letter: "On the Continent 'glandular fever' is often applied to the disease in children, and 'infectious mononucleosis' to the disease in adolescents and adults, but the identity of the two forms is accepted." In answer to their criticism I have searched the literature for evidence in support of my argument. I can find no more telling support than that from the pen of Sir Henry Tidy himself, in an article on infectious mononucleosis in a recent number of the *Practitioner* (1945, pp. 355, 361, et seq.).

"Glandular Fever in Children.—This is the form in which glandular fever was first recognized. It is especially common in England, in resident preparatory schools, between the ages of 8 and 14."

"Glandular Fever in Adolescents: Infectious Mononucleosis.—This is the form in which glandular fever is commonly recognized in America, usually among college students. American accounts of the disease are essentially based on this group."

Later, discussing the heterophil agglutination test, its value and application, Sir Henry states:

"The question arises whether or not two types of glandular fever exist giving respectively positive and negative agglutinations. In view of the factors mentioned above [i.e., in the article] and technical difficulties connected with the test it cannot be expected that every case or series of cases should give positive reactions. There is nothing inherently improbable in the existence of two viruses, and some of the reports are difficult to explain otherwise" [my italics].

Perhaps Sir Henry omitted to inform Dr. Morley of this opinion before they wrote the final sentence of their letter: "Anyone who reads the literature under the impression that glandular fever and infectious mononucleosis are different conditions will arrive at an unfortunate state of confusion."—I am, etc.,

T. S. EINERL.

Jittery Legs

SIR.—It was with some surprise that I learned from your annotation on jittery legs (Jan. 19, p. 95) that I had for several years been suffering from a condition which had been solemnly named, not only in Latin but in French. I have always called it "creepy legs," and your second paragraph is a masterly description of the symptoms, with the milder of which I am

familiar. I think there may be a considerable psychological element present, as in my case an attack seldom begins before I have thought, "I wonder if I shall have it to-night?"

During an attack the "creeps" can be stopped by concentrating one's mind on stopping them, but as soon as the mind wanders from the subject a "creep" results. A common predisposing cause is the presence of local irritation such as the tickle of Army blankets or a gnat-bite. I have not been able to satisfy myself that any muscular contraction occurs, but after inhibition of the sensation for some time by what one must call "mental concentration" the muscles of the affected leg feel very tired. To the various contrivances suggested for stopping an attack I can add clenching the toes tightly and very vigorous—even painful—massage of the affected part, either of which may or may not have the desired effect. Although this condition has from time to time cost me many hours' sleep I have never taken it sufficiently seriously to try the effect of drugs, but now that I know it has been dignified as a syndrome I shall have to see what can be done along these lines. Since, however, the attacks are intermittent and unpredictable the assessment of the results will not be easy.—I am, etc.,

"—273."

SIR,—From my own experience of the many minor discomforts to which the flesh is heir, jittery legs is one of the most annoying. I suffered considerably in this way during my first pregnancy; the symptoms cleared up, only to recur with increasing severity during the next pregnancy, and then persisted for the following six or seven years. Medical opinions, inside and outside the family, were vague, and not helpful as regards treatment. However, I did gain complete relief from a course of iron and vitamins, which was prescribed for a definite secondary anaemia (confirmed by blood count). Once the count reached normal the "jitters" stopped.

I am writing this in case such a line of treatment would help other cases. The diagnosis of the anaemia was arrived at accidentally. I was in good general health. Having "jittery legs" sounds a stupid form of complaint, but it can be a real burden physically, mentally, and socially, and like chilblains is one of the things for which the medical profession offers sympathy but little relief.—I am, etc.,

"A DOCTOR'S WIFE."

Bitterness

SIR,—Mr. H. B. Stallard wrote a letter to the *Journal* under the above heading on Sept. 22, and I consider that the time is now ripe to re-emphasize what he then said. His letter has evoked sympathetic replies, but the matter is of such obvious importance to the reorganization of post-war medicine in Britain that no apology is necessary in bringing it up again. By not practising in Britain and therefore having no axe to grind, and further by not being myself an Englishman, I can state the facts without prejudice and without the reserve and understatement which are recognized English characteristics.

If the established doctor who has not himself served in the Forces fails really to understand at least something of what the war has meant to his colleagues now demobilized after years of service, it will be impossible for bitterness to be avoided.

And recent correspondence in medical journals strongly suggests that this is the case. There are facts that he can readily understand. He can understand the difference in income between £1,000 and, say, £3,000 a year. He can understand the financial difference in running two "homes" (life in the Army is not gratis) and also possibly retaining consulting rooms. He can perhaps understand the sordid conditions of troopship and camp. He can appreciate the opportunity the established non-serving doctor had to acquire property and to increase investments, and that the young non-serving doctor had to acquire higher qualifications. He can understand the difficulties and anxieties of a colleague returning to a complex job similar to his own but a job with which he has grown completely out of touch but from which he must earn his living in highly competitive conditions and without the financial backing that he would have accumulated had he remained in private practice. These facts the civilian doctor can understand, and it is well that he should ever bear them in mind.

But there are facts that it is not possible for him fully to understand, for the understanding of them demands personal experience. He cannot understand the endless frustrations, futilities, and "fighting-one's-own-side" that have so embittered the Army doctor. It is likewise impossible for him to understand the "being-treated-like-a-schoolboy," the lack of individual freedom, and the squashing of initiative which, combined with the above, have so influenced him against any form of State control in medicine. He may partially understand these, but he certainly cannot understand the bitterness of separation from wife and home, from friends, from his busy useful existence and established way of life—leaving all this and returning to the community discipline of school days—and this separation being often absolute for years. These can be understood only by personal experience, but it is essential that the civilian doctor should keenly recollect and make allowances for them when planning with his demobilized colleague. Without a sincere appreciation of these facts and without full consideration being given to them, bitterness either publicly stated or inwardly nurtured, is bound to ensue.

The European medical world with its shattered universities and scattered students will look to England for guidance and help in medical advance. Such England cannot give if her planning is frustrated by the bitterness of the war years. Let the civilian doctor, therefore, be certain to show his demobilized colleague, in both precept and practice, that he has a real understanding of the inequality of sacrifice and thus prevent the latter from allowing the barrier of bitterness to arise between them. There is no other way.—I am, etc.,

An Association of Medical Societies of the United Nations?

SIR,—May I suggest that the medical societies of Great Britain take the opportunity of the United Nations Delegations Meeting in London to propose and to start the foundation of an "Association of Medical Societies of the United Nations," to which the individual medical societies of the various countries should be affiliated? This association could serve as a clearing house for the exchange of medical experiences in public health, medical practice, and medical research by the exchange of literature, by communication of statistical facts, and by the organization of international meetings. It may also have to take up some of the duties of the health department from the deceased League of Nations at Geneva. Another useful purpose would be facilities for the exchange of medical students, teachers, and research workers between the different countries. Further to that it will ease a decision to be taken at the appropriate time about the admission of medical societies of former enemy countries.—I am, etc.,

London. W.1.

E. M. FRAENKEL.

Czechoslovakia's Need for Textbooks

SIR,—On Nov. 17, 1939, the Charles University in Prague was closed by the German occupying authorities. This was but one of the measures adopted by them all over Czechoslovakia for the purpose of destroying the intellectual leadership of the Czech people and eliminating the university centres of resistance. The execution of professors and student leaders, the imprisonment and suffering of thousands of others, make a story already well known. The difficulties of this period of reconstruction are, however, less well publicized and thus less widely understood.

The universities opened again at the liberation. Ninety professors and ten lecturers from the Universities of Prague and Brno did not return from camps and prisons. There were fewer teachers and more students than ever. Over 60,000 students, many of whom had passed over six years in exile as soldiers fighting with the British and Russian Armies or in forced labour in Germany and Czechoslovakia, were waiting to begin or continue their university courses. In these circumstances there were many serious problems for all: ill-health, fatigue, and shortage of food and fuel, which are general problems, and others which are peculiar to students. The Czechoslovak youth tackled their own difficulties with resource, courage, and originality. There was no coal to heat their university build-

ings, lecture rooms, and hostels. Therefore teams from 1,500 students worked in shifts in the mines. There was insufficient accommodation in the lecture hall for all who wished to attend. Priorities were given by the Students' Union to resistance members and to older students. Lectures were broadcast into adjoining rooms. No new textbooks had been printed since 1939, and the Nazis had robbed the libraries of the university.

Recently, with another representative of the British Medical Students' Association, M. H. Lessof, former International Secretary, I attended the first post-war World Students' Congress in Prague. We saw and learned these facts for ourselves. We have in our possession copies of the textbooks, printed by themselves, which the students now have to use. They consist of duplicated typewritten sheets in a loose folder reproducing lecture notes and articles from professors and lecturers. In textbooks of biology and medicine, identical with those described, only the simplest diagrams can be reproduced. All of these facts, together with those circumstances of war and occupation which have for six years cut off Occupied Europe from all recent developments in science and medicine, constitute to-day a serious check and embarrassment to study.

During the war many Czech students have been in England and many more have learned English in order to listen to B.B.C. broadcasts. There is, therefore, reason to believe that textbooks sent from this country will have a greater value than that simply of a gesture of friendship. The British Medical Students' Association is, therefore, organizing a collection of medical and scientific textbooks to be sent to a students' reading-room in Prague. We wish to appeal most strongly to all who have in their possession used textbooks on medical subjects, on the natural sciences, or of general scientific interest to send them to us. We should be equally glad of copies of medical and scientific journals and of book tokens to procure new copies of standard works. The books most needed are: illustrated textbooks of biology and histology; textbooks of anatomy, anatomical atlases; books incorporating recent advances. Gifts should be addressed to:

The British Medical Students' Association,
B.M.A. House, Tavistock Square,
London, W.C.1.

We hope later to extend our distribution of books to other countries. Therefore we hope that this present appeal will arouse wide interest and support.—I am, etc.,

London, W.C.1

T. A. MADDEN,
International Secretary, B.M.S.A.

Increasing the Number of Doctors

SIR.—Dr. Maurice Shaw (Jan. 12, p. 64), referring to your comment on Prof. Ryle's letter that the proper solution of the problem of distribution of doctors is an increase in their numbers, maintains that the projected arrangements for admission of more women students to the hospital is likely to decrease rather than increase the number of doctors. I do not wish to express an opinion on this aspect of the problem, but when more doctors are unquestionably needed the risk of any decrease of numbers resulting from the measures taken calls for most careful consideration. Whether the admission of a greater proportion of women to our medical schools will result in an ultimate decrease, or lack of increase, in the number of doctors may be debatable, but at this time it surely is inadvisable to take away permission to continue practice here from the alien doctors, "enemy" and friendly, who have proved themselves during our years of desperate need. I understand the period during which these doctors may continue to practise here has been extended to the end of the year, but this is not sufficient. As I have previously pointed out, these men and women have already undergone much suffering and anxiety—the Nuremberg trials tell us how unbelievably much—and I plead that their anxiety for the future should now be put at rest by giving them permission to continue to practise here with full professional status. If this is not to be granted this decision should be made known to them so that they may plan the remainder of their broken lives. I appeal for friendly as well as "enemy" alien doctors, since owing to the revolutionary changes that have taken place in Europe many of the former do not wish to return to their native lands.—I am, etc.,

London W 8

HAROLD H. SANGUNETTI.

A Fundamental Principle

SIR.—In the letters which you have recently published on direction of doctors one important point appears to have been overlooked by all your correspondents. There are, in fact, no such organic entities as State or the "community," these being simply convenient abbreviations for all the people living in a given administrative area, such as Great Britain. From this it follows that if one group of people, such as doctors, are to be ordered about for the benefit of the State or the "community," they are in reality, merely being exploited in exactly the same way that slaves are exploited, for the benefit of some of their fellows. If it is indeed desirable to secure more doctors in certain unattractive areas the only equitable way in which the people of these areas can secure medical service is to pay for it at more attractive rates than in other parts of the country. In the conditions of medical practice and the remuneration are made sufficiently desirable there will obviously be no difficulty in securing doctors in any area, but if these conditions are not met and doctors are sent there to practise willy-nilly, then I can see no fundamental moral distinction between this and any other form of slavery or exploitation.—I am, etc.,

W. J. SUPER-MARE

CYRIL G. EASTWOOD,
Medical Officer of Health

SIR.—Mr Eric Coldrey (Jan. 12, p. 63) makes one very important point when he says how unlikely it is that high-ranking planners will ever come within their own plans. Examples from past and present are all against it. When the system of compulsory instruction was instituted in 1870 educationists realized that it was not education as understood hitherto. The proof of that is that the planners of that day who instituted the system did not have their own children submitted to it. So with the system of compulsory health insurance which began in 1912. There is plenty of evidence that behind the façade of Nazism and Communism in Germany and Russia the high-ranking Nazis and Communists had, or have, private fortunes, private houses, and private medical practice—that is, they demand what is normal and natural to any man brought up in the normal European tradition; they deny these things to the serfs alone who are their planning fodder. We are making for a society which will be rotten at the top and rotten at the bottom. It will be rotten at the bottom because there seems no limit to the conditioning of the workers, body and soul which will be attempted. The Lloyd George plan took 4d. from the worker's weekly wage. The current plan contemplates deducting 4s. to be held against the good behaviour in the future—i.e., submission to what the planning classes consider good for him.

Consider the position of an ambitious young planner in one of the Ministries, say, twenty years hence, what will there be for him to do but to propose some further conditioning of the worker, provided by further deduction from the worker's wages? For by that time the machinery of exaction and compulsion and conditioning will be working smoothly. I think that one may safely predict that the English will not breed in that captivity. (There is evidence that even among races with a long tradition of slavery, planned serfdom of the modern type is immensely destructive of nations.) A society of that kind is rotten at the top, because planners, with immense powers to condition the minds and bodies of the people, tend to respect no law but their own ambitions.

In such a society the medical profession will be very easy meat for the politicians and the high-ranking officials. If medical men surrender the position of acting as principals in a relation in which no third party—and certainly not the State—has a right to interfere, and betray the claim of the patient to be regarded likewise as a principal, they will lose status, and the teaching of all history is that loss of status is followed by loss of economic position.—I am, etc.,

Stamford Hill, N 16

E. H. STANGE.

SIR.—It would be as well to know what exactly Prof. Ryle does mean by direction of doctors. He appears now to limit it to young doctors. What about consultants and specialists? In his letter (Jan. 19, p. 105) he says: "If men will not volunteer for certain areas some will have to be posted, just as they are already posted in the Services and Colonies." He appears

to ignore the fact that under normal conditions men can at any time resign from appointments and take up other work, but under the conditions he visualizes that would be possible only if permitted to do so, as all medical practice, both at home and abroad, would be at bureaucratic disposal. His agreement that in certain areas the conditions of practice must be improved in order to attract doctors is, of course, obvious, but in giving his personal opinion that such improvement could best be made in an organized service employing full-time doctors he is evidently not concerned with the suitability for the profession of doctors who would consent to this arbitrary disposal of their lives.

It would also appear that Prof. Ryle is of opinion that such organization as is necessary when the servitude of the nation to a foreign Power is at stake is comparable to arrangements under normal conditions.—I am, etc.,

St. Mawes.

B. H. SHAW.

SIR,—“A State Medical Service. How it can be done.” After much consideration of this important subject and a perusal of many letters I have come to the following conclusion.

The only way to make such a service a success is to form immediately a non-sectarian order of monks and nuns sworn to celibacy and poverty and devoted exclusively to the practice of medicine. This accomplished, Prof. J. A. Ryle, Vicar-General of the Order, from his headquarters in the slummiest and most smoke-begrimed district of the ugliest and most uncouth city of the country—whether it be North or South or East or West, on the doorstep of Oxford or three hundred miles from it—can direct the devoted practitioners of his certificate-enveloped, red-tape-strangled art and science to wherever fate and standing committees deem them to be required, whether it be for years or for ever, or for but a day.—I am, etc.,

St. Albans.

OLIVER SLOAN.

Medico-Legal

MENTAL HEALTH LEGISLATION IN EIRE

A new Mental Treatment Act is being brought into operation early this year in Eire. It is an Act of 284 sections and repeals 19 previous enactments from 1821 to 1942; in fact, all existing Acts are repealed except those relating to criminal lunatics and to persons of unsound mind who are wards of court. It marks a departure from previous legislation and from the existing British code in several respects, notably in the machinery for admission of patients into mental institutions; the judicial authority necessary for such admissions is removed and the procedure is wholly medical.

Admission to Mental Institutions

When it is considered necessary to have a person admitted to a mental hospital, and he cannot afford the whole cost of his medical assistance, application is made by a relative or other person to the medical officer of the dispensary district in which he lives, whereupon the M.O. visits and examines him and, if he thinks proper, recommends his conveyance to the district mental hospital. Here the resident medical superintendent or another medical officer on his behalf is required to examine him, and if he is satisfied that the patient is of unsound mind he makes an order for his reception into detention. Similarly a member of the *Garda Síochána* (police) considers it necessary that a person believed to be of unsound mind should for safety reasons be placed under care may take him into custody and apply to the district M.O. for a recommendation, when the same procedure is followed. Again, if an assistance officer learns that such a person is not under proper care or control or is neglected or cruelly treated he may apply in the same way to the M.O.

In the case of a private patient whom it is thought desirable to detain in a private institution, application is made by a relative or some other person to a medical practitioner for an order. The practitioner accepting the application must arrange with another practitioner that each of them shall separately examine the person, and only if each is separately satisfied that it is proper to make an order shall an order be made. This must state that the person concerned is of unsound mind, is an appropriate person to be taken charge of and detained for care and treatment, and is unlikely to recover within six months. The facts on which these conclusions are reached must also be stated, and it must be indicated which facts

have been observed personally by the certifying practitioners and which have been communicated to them by others. It is also provided that certain persons must not make either the application or the order; these include members of the governing body of the institution, those who may have an interest in the payments to be made for the care of the person, and practitioners regularly attending at the institution. If a person, having been detained in the institution, escapes he may again be detained if retaken within 28 days.

Temporary and Voluntary Patients

Provision is also made for the admission of temporary patients—chargeable or private—into approved institutions (which may include special departments of voluntary and municipal hospitals) so that advice and treatment may be obtained without a mental hospital being entered. The district medical officer must certify in the case of the chargeable patient, and two medical practitioners in that of the private patient, that he is suffering from mental illness, that he requires for his recovery not more than six months' suitable treatment, and that he is unfit by reason of his mental state for treatment as a voluntary patient, or that he is an addict and requires for his recovery at least six months' preventive and curative treatment. This inclusion of provision for addicts is regarded by psychiatrists in Eire as a very welcome part of the Act. An addict is a person who by reason of addiction to drugs or intoxicants is dangerous to himself or to others or incapable of managing his affairs, or one who, by reason of addiction to drugs, intoxicants, or perverted conduct, is in serious danger of mental disorder.

If the chief medical officer of an institution becomes of opinion that a person detained under a temporary order will not have recovered at the end of six months he may request the Minister of Local Government and Public Health to extend the period by further periods of six months, but not to a greater extension than eighteen months—a more expeditious procedure than that followed in England and Wales under the Mental Treatment Act, 1930. It is anticipated that the vast majority of patients other than voluntary ones will be received as temporary patients.

Voluntary patients may themselves (or through their parents or guardians if they are under 16) apply to be received in an approved institution, the application being accompanied by the recommendation of a doctor who has examined them. Such patients may give notice that they wish to leave the institution within 72 hours. If while being treated they become mentally incapable of expressing themselves as willing or not willing to remain, they may be discharged into such custody as the person in charge of the institution approves. Absence on parole may be permitted for 30 days, and the period may be extended.

Mental Clinics

Other provisions are designed to simplify the transfer of patients for special treatment from one hospital to another, to allow the authorities to board-out patients, and to require private institutions to be registered by the Minister instead of, as formerly, to be licensed by judges. Mental hospital authorities are to be allowed to establish consulting-rooms or clinics at the mental hospital or elsewhere at which advice and preventive or curative treatment may be given. Private patients attending such clinics will be charged for attendance on a scale approved by the Minister. Two or more mental hospital authorities, with the Minister's consent or at his direction, may maintain jointly an institution for any class of patients who are not dangerous to themselves or to others, and a joint authority may be set up for the management of such institutions. It is hoped that this provision will be widely used in any future scheme for development and extension of mental hospitals. A former Act provided that two or more district mental hospitals might unite in providing a laboratory for pathological research. This provision was never taken up; it is now re-enacted, with the addition that the authorities must make such provision if the Minister directs. Eighteen mental hospital districts are set up under the Act, corresponding to counties or unions of two counties with their county boroughs.

Dr. Joseph Kearney, Inspector of Mental Hospitals, Local Government Department, Dublin, states that the Act has been welcomed by psychiatrists generally and has received unstinted praise from the Irish Branch of the Royal Medico-Psychological Association. He adds: “It seems justifiable to hope that when its various provisions are made effective we shall have in this country a statutory code well in advance of corresponding provisions in other countries.”

Dr. Joseph Paynter Holt, former associate professor of physiology at the University of Louisville, has joined the medical department of the Standard Oil Company (New Jersey) as a specialist in toxicology. He will be responsible for research into the biological effects of toxic substances.

Obituary

W E THOMAS MD JP

We have to announce with much regret the death of William Evans Thomas of Ystrad Rhondda Glamorganshire a veteran member of the British Medical Association who did fine work for his colleagues in Wales and had been a member of the Central Council from 1923 to 1944 and before then regularly attended meetings of the Representative Body for eighteen years. He joined the B.M.A. in 1891 and served on many committees and subcommittees at headquarters in his longest periods of service being on the Welsh Committee and the Insurance Acts Committee from 1919 to 1944. When the Association met at Cardiff in 1928 he held office as president of the Section of Medical Sociology, and no Annual Meeting seemed complete without his personal presence. Dr. Thomas graduated M.B., Ch.B. at the University of Edinburgh in 1888 and took his M.D. in 1892. He was a Justice of the Peace for the county of Glamorgan and served as High Sheriff of Merioneth in 1927-8.

Dr A T JONES past president of the South Wales and Monmouthshire Branch sends the following tribute

This country, and Wales in particular, has lost a great leader in the medical fraternity by the death of Dr W E Thomas J P of the Rhondda, South Wales. He was known and referred to by nearly everybody as WE. He came to the Rhondda as an assistant to Dr James nearly sixty years ago and succeeded to the practice at his death. He married one of Dr James's daughters. The practice grew very extensively and Dr Thomas had to engage three and sometimes four, assistants. His main surgery was at Llysgrais and he had two or three branch surgeries. He was an indefatigable worker and gave personal attention to all his patients. He loved his profession and was kind, sympathetic, and considerate to those who suffered. He was keenly interested in any advancement and development in the art of medicine. He held several appointments, such as district medical officer, public vaccinator, and visiting medical officer and surgeon to the Llynypia Hospital, which latter post he held until the County Council appointed a resident surgeon to the hospital, Dr Melbourne Thomas, who is still resident medical officer of the institution. Outside his profession he took a keen interest in social and political activities. He was a member of the Rhondda District Council, a County Councillor, and Alderman of the Glamorgan County Council. He held these posts for many years until he decided to retire and give up public work.

Dr Thomas was a good, sound practical medical practitioner. He was a member of the Insurance Committee for Glamorgan from its inception and chairman of the Panel and Local Medical Committee from the start. He was a true leader of the profession, reliable and solid in his advice and leadership, especially at the time when the Insurance Act of 1912 came into force. He took an active part in affairs of the British Medical Association, being for many years the representative of the North Glamorgan and Brecknock Division. He was also a member of the Central Council and was re-elected annually for a number of years, he attended the meetings regularly and was active in their deliberations. He was a member of the Insurance Acts Committee, to which he was elected annually as one of two representatives for Wales. He was of course elected president of the South Wales and Monmouthshire Branch, which office he filled with dignity and ability. After the completion of fifty years in practice he was elected president of the Branch for a second time in 1935. This proves the esteem in which Dr Thomas was held by the members of the Branch.

"WE" was a most loyal man and was truly sympathetic to his colleagues and friends. He was ever ready to help anyone in difficulty. Mrs. Thomas, his first wife, died in about 1932. He married for the second time and his wife has proved herself a devoted helpmeet. He lost his two daughters, one a girl of 19 and the other a girl of 14. These as I know personally were severe blows to him. He is survived by one son. Dr. Thomas had reached the mature age of 82. He had

suffered physically, for the last few months, but he was mentally alert and as a friend and admirer of his, I saw his death as a grievous loss when our profession is passing through a critical period in its history.

Dr EDWARD ANGEL GAYNES DOYLE who died in retirement at Watford Heath, Hert. on Jan 21, had been a member of the British Medical Association for 62 years. Born in 1860, he studied medicine in London at the Westminster Hospital and took the M.P.C.S. and L.P.C.P. diplomas in 1885. Dr Doyle practised for many years at San Fernando in the island of Trinidad and had held the posts of medical officer for South America and San Fernando and resident surgeon to the Trinidad Colonial Hospitals. He was president of the Trinidad Branch of the B.M.A. in 1922-5.

Universities and Colleges

UNIVERSITY OF OXFORD

The Board of Management invites candidates for the Francis Gotch Memorial Prize for the examination for which will take place on Saturday, March 2 at 2.20 p.m. in the University Department of Physics, Oxford. Candidates are requested to send in their names and qualifications to the Board of Management, University Department of Physics, Oxford by Saturday, Feb 22.

In a Congregation held on Dec 15, 1945, the degree of D M was conferred on G R Gurdlestone

In a Commencement held on Dec 22 the following degrees were conferred

M. C. — B. B. H. ^{NY}
 B. M. B. C. H. — R. P. d. d. c. West L. D. Hamilton R. Gilman H. A. S. Powland,
 M. P. d. c. H. T. ex. G. M. Woodman, Al. d. c. E. M. M. R. B. d. c. h. Pamela
 F. M. C. d. c. S. d. c. J. N. d. c. h. E. H. H. d. c. d. c. Hilar J. E. Allen, Elizabeth
 P. d. c. h. L. c. ^{NY} Helen M. W. d. c. ^{NY}

UNIVERSITY OF LONDON

D. A. Goss (Ph.D./Econ), has been appointed to the University Post in Demography, tenable at the London School of Economics and Political Science. He has worked in the Social Biology Department of the School, and in 1976-40 was research fellow of the Population Investigation Committee.

The following candidates have been approved at the examinations indicated:

C J S - Far W M L Turner H Wolfsohn Branch II (Public Health) J H H
Kall R F Welch Branch IV (Malaria and Diseases of Women) L W
Hefernan Branch I (Hygiene) W Taylor

UNIVERSITY OF GLASGOW

Intensive postgraduate courses in medicine and in surgery, consisting of clinical meetings and lectures, will be conducted from March 11 to April 13. As numbers will be restricted those wishing to attend should make early application to the Convenor, Committee on Postgraduate Medical Education, the University, Glasgow, W.2, from whom copies of the syllabus for the courses may be obtained. The fee for either course is fifteen guineas.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following anatomy lectures will be delivered at the College (Lincoln's Inn Fields, W.C.) at 5 p.m. on each day: Feb. 4, 6, 7, 11, 13, and 14, Prof. F. Wood Jones, F.R.S., six lectures on oology; Feb. 18, 20, 21, 25, 27, and 28, Prof. A. J. E. Cave, six lectures on the anatomy of the head and neck. Fellows and Members of the College will be admitted free of charge on signing the attendance register. The fee for others is as follows: Anatomy course (Feb.) £2.2s applied physiology course (March) £2.2s, pathology course (March) £2.2s. A composition fee of £5.5s may be paid for all three courses. Tickets may be obtained on application to the secretary, of the College.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF
GLASGOW

Prof F A E Crew, M.D., F.R.S., will deliver the Finlayson Memorial Lecture on "Medico-sociological Problems of an Aged Population" in the hall of the Royal Faculty of Physicians and Surgeons, 122, St Vincent Street, Glasgow, on Wednesday next, Feb 6, at 4 p.m.

SOCIETY OF APOTHECARIES OF LONDON

At a meeting of the Court of Assistants, held recently with the Master, Dr. Hugh F. Powell, in the chair, the death of Sir Farguhar

Buzzard, Honorary Freeman of the Society, was received with great regret.

Dr. J. P. Hedley was appointed representative of the society on the General Medical Council, and Mr. L. Vernon Cargill on the Chelsea Physic Garden Committee.

A handsome bronze rhinoceros (as depicted on the society's crest) was presented by Dr. C. R. Box, and medical books and instruments were received from the estate of the late Dr. E. S. White, Liveryman.

The Diploma of Mastery of Midwifery was granted *honoris causa* to Mr. Arthur C. H. Bell, late Examiner.

The following were appointed Examiners to the society in the subjects named: *Midwifery*, Dr. W. N. Searle; *Mastery of Midwifery (Paediatrics)*, Dr. R. W. B. Ellis; *Materia Medica and Pharmacology*, Dr. C. A. Keele; *Diploma in Industrial Health*, Dr. A. J. Amor, Dr. J. C. Bridge, Prof. F. A. E. Crew, Dr. Margaret Dobbie-Bateman, Dr. M. W. Goldblatt, Dr. E. R. A. Merewether.

The Diploma was granted after examination to the following candidates: G. C. Mayer, B. Dawes, C. J. W. Soutar, T. J. Thompson, M. W. Johnston, D. Wimborne, J. C. Matthews, R. G. G. Jones, I. H. Mercer, F. J. Offord, R. A. Wilkinson, R. C. Jennings, D. D. Forbes, B. H. Pickard, P. J. Roden, J. Flintner, R. J. C. Hutchinson, R. Clitherow.

The Services

The American Bronze Star for meritorious service has been awarded to Major William Robert Henderson, late R.A.M.C., for saving American lives while he was a prisoner of war in Germany from May, 1940, to May, 1945.

Temp. Surg. Lieut. R. A. de K. Glover, R.N.V.R., has been mentioned in dispatches for good service, efficiency, and zeal while serving in H.M.S. *Easton* during operations in the Aegean from Sept. to Dec., 1944, including the landing of Royal Marine Commandos at Cape Psalis and the bombardment, in the Athens-Piraeus area.

The following have been awarded the R.N.V.R. Officers' Decoration: Surg. Cmdr. M. Godwin, and Surg. Lieut.-Cmdrs. R. F. B. Bennett, E. E. Henderson, R. D. Jenkins, D. R. Hughes, P. M. Coats, and A. I. L. Maitland, R.N.V.R.

Col. R. W. Richardson, E.D., R.C.A.M.C., has been appointed O.B.E. (Military Division), and Major (Acting) T. A. Gander and Capt. E. C. Vandervoort, R.C.A.M.C., have been appointed M.B.E. (Military Division), in recognition of gallant and distinguished services in Italy.

Capt. (Temp. Major) G. C. K. Reid, R.A.M.C., has been granted a King's Commendation for brave conduct.

Capt. J. R. S. Third, R.A.M.C., has been mentioned in dispatches in recognition of gallant and distinguished services while a prisoner of war.

The Order of the Star of Nepal, Fourth Class Honorary (with the title of Manya Nepal Tara), has been conferred upon Capt. H. N. Roy, I.M.S., and Capt. N. Uddin.

The following appointments and awards have been announced in recognition of gallant and distinguished services in North-West Europe:

K.B.E. (Military Division).—Major-Gen. E. Phillips, C.B., C.B.E., D.S.O., M.C., late R.A.M.C.

C.B.E. (Military Division).—Brig. (Local) R. K. Debenham, O.B.E., and Brig. (Acting) G. K. Fulton, M.B.E., R.A.M.C.

O.B.E. (Military Division).—Cols. (Acting) W. D. Jackson, M.C., and F. C. Miller, M.C., Col. (Temp.) A. R. Oram, M.C., Lieut.-Col.

P. Rutherford, T.D., Lieut.-Col. (Acting) H. V. Brennan, and Lieut.-ls. (Temp.) C. Bainbridge, J. C. Caird, R. S. Handley, S. Heatley,

Heiler, G. H. G. Hope, M.C., D. F. Hutchinson, G. A. Kane, A. G. R. Lowdon, R. L. Mackay, G. A. G. Mitchell, J. Neill,

G. W. Saunders, H. Sissons, J. M. Tait, and F. W. A. Warren, D., R.A.M.C. Cols. W. A. Jones and G. E. Wight, Col. (Acting)

C. Ross, Lieut.-Col.s. J. A. Dauphinee, M. R. Elliott, R. B. Kerr, and F. L. Shipp, and Lieut.-Col. (Acting) J. B. Bundock, R.C.A.M.C.

M.B.E. (Military Division).—Lieut.-Cols. (Acting) K. E. A. Hughes and R. Paul, Lieut.-Col. (Temp.) R. J. Phillips, Majors

W. H. Scriven and A. P. D. Thomson; Majors (Temp.) I. Aubrey, M.C., S. O. Ayett, R. Barraclough, J. Bleakley, P. W. H. Bleasdale,

J. A. C. Burridge, G. B. Carter, W. N. Chisholm, C. H. Davies, M. H. A. Davison, P. F. Dedow, C. M. Elliot, G. W. Hearn, G. A. Hodgson, A. E. Loden, H. H. I. Pearson, H. G. Percy, S. F. Raistrick, W. D. Richardson, G. M. Ross, C. I. Tuckett, R. H.

Webber, C. J. Wells, and K. S. Wilson; Capt.s. R. W. Clarke, P. J. Hardie, R. B. McGrigor, D. D. Muir, and Agnes D. D. Murray;

Lieut.s. R. J. Hughes, W. Mills, and J. C. E. Sundell, R.A.M.C. Majors N. J. England, D. K. Grant, H. I. Palmer, W. S. Keith,

F. J. McLean, J. B. Neilson, and A. F. W. Peart; Majors (Acting)

W. F. Bie, W. F. H. O'Neill, and R. L. Reeves; Capt.s. F. A. Jennings, H. A. Roberts, N. Kaufman, G. C. Sweet, and J. C. G. Young, R.C.A.M.C.

First Bar to the D.S.O.—Col. (Temp.) M. MacEwan, D.S.O., O.B.E., D.F.C., T.D., R.A.M.C.

D.S.O.—Lieut.-Col. M. H. Summers, T.D., and Lieut.-Cols. (Temp.) W. M. E. Anderson, A. Cowie, and E. H. P. Lassen, R.A.M.C.

M.C.—Major (Temp.) J. C. Watts and Capt.s. K. W. Beetham, L. S. Cooper, J. H. Haldane, H. M. Kershaw, G. H. McPherson, H. E. S. Marshall, J. G. Mott, C. T. H. Whiteside, and W. J. W. Wolfe; Lieut. W. J. Gallagher, R.A.M.C. Capt.s. B. L. P. Brosseau and W. M. Byers, R.C.A.M.C.

Medical Notes in Parliament

Nursing Shortage

THE EARL OF MANSFIELD in the House of Lords on Jan. 24 asked if the Government knew that a number of hospitals had been compelled to close one or more wards owing to shortage of nursing staff, and even so were unable to avoid the nurses having to work such long hours that their health suffered. He asked what the Government was doing to remedy this, and whether it was prepared at once to close redundant military hospitals and to transfer sufficient nurses to ease the situation in civil hospitals.

THE EARL OF LISTOWEL said the Government had taken certain measures to increase the supply of nurses, including the adoption from Jan. 1 of improved scales of salaries and the issue of a circular to hospital authorities urging increased employment of male nurses with special reference to those returned from the Forces and the establishment of more training schools for men. He said the powers of direction and control of engagement of nurses and other persons who had more than a year's recent nursing experience, and of midwives, were being retained for six months beyond Dec. 20, 1945, but no longer, to ensure that nurses and midwives were distributed between the health services according to need. He understood from Mr. Lawson that military hospitals were being reduced in size as quickly as equipped beds became surplus to establishment. Nursing officers were being released from the Army according to a programme based on a bare-sufficiency being retained for the nursing requirements of the Army. Over 3,100 nursing officers of the Q.A.I.M.N.S. and some 2,000 V.A.D.s had been released or discharged up to the end of Nov., 1945.

Refresher Courses

SIR ERNEST GRAHAM-LITTLE asked on Jan. 22 whether the Secretary for War was aware that medical officers about to be released from the Services required to spend some considerable time in refresher courses to fit them for undertaking civil practice; and whether he would arrange with the Minister of Health that these courses should be provided and followed by such officers before being admitted to civil practice. Mr. LAWSON answered that all medical officers released from the Army were informed of the facilities available under the Government's scheme for postgraduate training and refresher courses. This scheme, common to all three Services, was drawn up by the Ministry of Health and the Department of Health for Scotland, in conjunction with the universities and other interested bodies. Every encouragement was given to medical officers to avail themselves of these facilities before entering civil practice.

Specialists in the R.A.F.

MR. STRACHEY told Sir E. Graham-Little on Jan. 23 that in the R.A.F. Medical Branch specialists were recognized as such when they acquired a higher medical qualification in their specialty and had been recognized as competent by the consultant concerned. Specialists had been employed since the formation of the R.A.F. in 1918, though the general use of the title grew up only during the recent war. It was now used when officers so qualified were appointed to established posts for specialists. Specialist pay did not follow recognition as a specialist in the R.A.F., but specialists normally received higher rank than non-specialist medical officers. This accorded with the recommendation of the report made in 1933 by the Committee on the Medical Branches of the Defence Services. Two specialists, one oto-rhino-laryngologist and one anaesthetist, each employed in this respective specialty, had been appointed to the R.A.F. Medical Branch since VJ-Day. They were both replacing specialists released in Class B. Specialists had been demobilized in their age-and-service groups up to Dec. 31, 1945, but since then no doctors had been allotted to the Royal Air Force, and the Force had to retain seven specialist officers who

were occupying established specialist posts until the Central Medical War Committee could provide replacements. One of them was already being relieved and would now be demobilized.

Health Service Discussions

Sir HENRY MORRIS-JONES on Jan 24 asked the Minister of Health whether he had yet started consultations with the representatives of the voluntary hospitals and the medical profession on the national health proposals, and whether the result of the discussions would be made public. Mr BEVAN said he was engaged in discussions with representatives of the medical profession, local authorities, voluntary hospitals, and others, to obtain their expert advice on his proposals for the National Health Service. His proposals would be published in the usual manner by the introduction of draft legislation for the approval of Parliament.

Major HUGH FRASER on Jan. 24 asked the Minister of Health to make a more precise statement on the future administration of British hospitals. Mr. BEVAN asked the members to await the presentation to Parliament of the Government's proposals.

Doctors on Pensions Boards.—On Jan 24 Air Commodore HARVEY asked how many medical officers employed in a full-time capacity by the E.M.S. were also employed and remunerated on a seasonal basis by the Ministry of Pensions for work on boards. He asked for an assurance that this practice would cease in view of the fact that medical men released from the Services were unable to obtain part-time employment on pensions boards. Mr PALING answered that so far as he was aware no such medical officers were employed by his Department at the present time.

Notes in Brief

Arrangements are being made to release from the Forces a small number of ophthalmic lens workers in Class B.

There is no prospect of any early increase in the soap ration.

The Government has not yet determined its permanent policy in regard to flour and bread.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases were more prevalent during the week. The increases were: acute pneumonia 280 more cases, whooping-cough 142, scarlet fever 105, dysentery 59, diphtheria 56, cerebrospinal fever 33.

The rise in scarlet fever was general, no area showing a large incidence. The increase in whooping-cough was in the northern section of the country. Diphtheria rose by 22 cases in Northampton C.B., by 14 in Lancashire, and by 13 in Durham; the only significant fall was Nottinghamshire 17. A large outbreak of measles in Southampton Port Health District involved 79 persons. During the past three weeks the numbers of cases of cerebrospinal fever have been 38, 53, and 86, these being spread over the country.

No fresh large outbreak of dysentery was reported during the week. A further 162 cases in the Melton Mowbray area of Leicestershire brings the total for the past three weeks to 414. The other noteworthy returns were Lancashire 36, London 28, Rutland 16, Northumberland 15, Yorks West Riding 13, Essex 11.

In *Scotland* large increases were recorded in the incidence of measles (124 more cases), acute primary pneumonia (72 more), whooping-cough (62 more). The only notable decreases were scarlet fever 37, and diphtheria 15. The fall in diphtheria was most marked in the western area; in other parts of the country there was a small general rise. Scarlet fever in Glasgow fell from 94 to 68.

In *Eire* the rises in measles (50 more cases) and whooping-cough (32 more) were mainly contributed by Dublin C.B., where there were also 17 more cases of diarrhoea and enteritis.

Vital Statistics of Manchester

The provisional return for last year showed that the maternal mortality rate, 1.48 per 1,000, was the lowest ever recorded in the city. The birth rate was 18.15, and the infant mortality 56.27 per 1,000 live births, these rates being 1.70 and 2.68 respectively above those of 1944. The general death rate was 14.49, an increase of 0.29 on that of the preceding year. The death rate from tuberculosis was 0.92, compared with 0.91 in 1944.

Week Ending January 19

The returns of infectious diseases in *England and Wales* during the week included: scarlet fever 1,251, diphtheria 478, measles 726, cerebrospinal fever 62, dysentery 371. One case of smallpox was imported into Southampton. Deaths from influenza in the great towns numbered 174.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan 12.

Figures of Principal Notifiable Diseases for the week, and those for the corresponding week last year, for (a) England and Wales (including London) (b) London (administrative county) (c) Scotland (d) Eire (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under the 1938-1940 and 1941-1942, are for (a) The 126 great towns in England and Wales (including London) (b) London (administrative county) (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases, a blank space denotes disease not notifiable or no return available.

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

Medical News

Dr. G. L. Brown will give an address on "Some Physiological Problems of Service at Sea" before the Royal Institution, 21, Albemarle Street, W., to-day (Friday, Feb. 1), at 5 p.m. The last three of a course of lectures on "Some Recent Advances in the Physiology of Vision" will be delivered by Prof. H. Hartridge, M.D., F.R.S., at the Royal Institution on Tuesdays, Feb. 5, 12, and 19, at 5.15 p.m. (The first lecture in this series was given on Jan. 29.)

A meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House, Tavistock Square, W.C., on Tuesday, Feb. 5, at 8.30 p.m., when Dr. Marjorie Warren will speak on "The Care of the Aged and Chronic Sick." On March 7 Miss Jocelyn Moore will speak on "Gynaecology in the Women's Services."

There will be a clinical meeting of the Medical Society of the L.C.C. Service on Thursday, Feb. 7, at 2.45 p.m., at Maudsley Hospital, Denmark Hill, when the members of the staff of the hospital will demonstrate cases.

Major-Gen. Sir John Megaw will deliver the Sir George Birdwood Memorial Lecture on "The Health of India" before the India and Burma Section of the Royal Society of Arts, John Adam Street, Adelphi, W.C.2, on Thursday next, Feb. 7, at 2.30 p.m.

Meetings of the West London Medico-Chirurgical Society have been arranged as follows: Feb. 15 and May 17, clinico-pathological meetings; March 15, Presidential address; and April 26, dinner-discussion. The Cavendish Lecture will be delivered in June. Details will be published later.

The Royal Society of Medicine has arranged a meeting jointly with the Scientific Film Association on Tuesday, Feb. 26, at 1, Wimpole Street, W.1, to discuss the place of films in medical education. The time-table is: 2.15 to 4.15 p.m., speakers on theory; 4.15, tea; 4.45 to 6.45, speakers on practice. The following have been invited to open the discussion: Mr. Patrick Meredith, Reader in Visual Education at University College of the South-West; Dr. H. K. Vernon, Chief Adviser in Psychology to the Admiralty; Prof. Winifred Cullis; and Dr. G. R. Hargreaves (late of Directorate of Army Psychiatry). It is hoped that many interested in technical adjuncts to medical education may be present.

A lecture on "War Experiences in Therapeutics" will be given by Prof. G. A. H. Buttle at the Pharmaceutical Society of Great Britain (17, Bloomsbury Square, W.C.) on Thursday, Feb. 14, at 7 p.m.

The Edinburgh Postgraduate Board for Medicine announces that the fourth 14-day general refresher course primarily for demobilized medical officers (Class 2) will start on Monday, March 18. Applications should be sent to the Director of Studies, Postgraduate Medical Board, University New Buildings, Edinburgh, 8.

Application is invited for Leverhulme Fellowships and grants in aid of research. These are intended for senior workers prevented by routine duties or pressure of other work from carrying out research. They are limited to British-born subjects normally resident in Great Britain, but in exceptional circumstances the trustees may waive the condition as to residence. The trustees will also consider applications from groups of workers engaged upon co-operative programmes of research, particularly from those engaged upon long-distance programmes or in institutions where the normal facilities for research have been curtailed by the war. The awards will not normally extend over more than two years or less than three months and the amount will depend on the nature of the research and the circumstances of the applicant. Forms of application may be obtained from the secretary, Dr. L. Haden Guest, M.P., Leverhulme Research Fellowships, 7, Bedford Row, London, W.C.1. Applications should be received by March 1, and awards will date from Sept. 1, 1946.

Dr. William Oswald Gibson Taylor is being invited by the Scottish Nationalist Party to contest the Cathcart (Glasgow) by-election caused by the death of Mr. Francis Beattie (Cons.). Dr. Taylor graduated M.B., Ch.B. at the University of Glasgow in 1934 and served during the war as an ophthalmic specialist in the R.A.M.C.

The Association of Austrian Doctors in Great Britain, which is affiliated to the Free Austrian Movement, has launched an urgent appeal to all colleagues in this country. Children, women, and old folk in Austria, survivors of concentration camps, will face not only hunger and cold this winter, but complete lack of the most essential drugs. Help is needed, and donations should be sent to the Aid to Austria Appeal Committee Medical Fund, 157, Bloomsbury House, Bloomsbury Street, London, W.C.1.

Mr. Samuel Davidson has been appointed honorary obstetric surgeon to the Birmingham Maternity Hospital to fill the vacancy caused by the death of Sir Beckwith Whitehouse, and Mr. R. W. Weedon Butler has been appointed honorary ophthalmic surgeon.

King Edward's Hospital Fund for London has received a further instalment of £125,000 from the Nuffield Trust for the Special Areas. In founding this trust Lord Nuffield provided that any sums that might be available by way of repayment of loans or otherwise from his Trust for the Special Areas should pass to the King's Fund. A total sum of £500,000 has now been received, the first £250,000 of which was, at Lord Nuffield's request, allocated to Guy's Hospital.

Mr. Ralph Bates, F.R.C.S., medical superintendent of Stoke Park Colony, has recently been appointed medical superintendent of the Royal Eastern Counties' Institution for the Mentally Defective, Essex Hall, Colchester.

A limited issue of penicillin lozenges is now being made for use in appropriate cases at hospitals. Medical practitioners will also be able to obtain a limited supply for carefully selected cases in their own practices by application to the nearest distributing centre.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to The EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Atiology Westcent, London*. ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London*. MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London*.

ANY QUESTIONS?

Treatment of Eunuchoidism

Q.—A man of 21 developed normally until the age of 14, when he suffered from mumps with bilateral orchitis. He is now worried by his smallness, high voice, and lack of beard. Females attract him, not males; he has occasional erections but no nocturnal emissions. There is "down" on his face, slight axillary hair, and a small clump of pubic hair, showing no signs of rising up the linea alba. His penis is that of a prepubertal youth. His testes are small, the right in the scrotum, the left at the external inguinal ring. What is the treatment?

A.—When bilateral orchitis is a complication of mumps recovery may be complete, or damage may be limited to the seminiferous tubules, or it may involve the interstitial cells of Leydig, which secrete testosterone. The seminiferous tubules are much more sensitive to toxins, and to high temperature, than are the interstitial cells, and the more usual condition, therefore, is normal virility but absence of fertility. However, in some cases, when the interstitial cells are also involved, one gets the condition of eunuchoidism, which is the clinical picture as described in the question. Treatment is by testosterone, which may be given as injections of the propionate, 50 mg. twice weekly, or as methyl testosterone tablets, 5 mg. t.d.s., or by implantation of testosterone propionate pellets subcutaneously, a total of 800 mg. being a suitable dosage.

Menstrual Migraine

Q.—A single lady aged 34 complains of intractable headaches starting some days before menstruation and lasting for about a week. The usual remedies have no effect, and the same applies to stilboestrol and gonadotrophin. It appears to be a pituitary type of headache. Menstruation is otherwise normal. Can you suggest a line of investigation and treatment?

A.—Cyclical headaches of this kind, sometimes described as menstrual migraine, may be of pituitary origin, but not necessarily. They are sometimes associated with high gonadotrophin and low oestrogen levels; gonadotrophic hormone therapy is therefore contra-indicated—it may make matters worse. Sometimes they are related to the retention of sodium and fluid in the tissues, and this in turn to a high oestrogen level in the blood. If, therefore, there is any sign of premenstrual oedema, distension, or increase in weight, oestrogens are also contraindicated. Many are the theories to account for the headache—swelling of the pituitary gland, cerebral anaemia, vasodilatation of cranial and cerebral blood vessels, hormone imbalance, allergy, neurosis. It would be of interest, if nothing more, to have the skull x-rayed to see if the roof of the pituitary fossa is calcified. A complete investigation of eyes, teeth, ears, sinuses, etc., as in any case of migraine, is also called for. Although oestrogens (including stilboestrol) and testosterone preparations administered

premenstrually are reported to be helpful sometimes, in general the results are disappointing. Treatment on more simple lines, aimed at reducing fluid retention and intracranial pressure, is often the best. Advise the patient to keep to a salt-free diet and to restrict her intake of fluid to 30 oz. (852 c.c.) in 24 hours, for seven to ten days premenstrually. Over the same period give ammonium chloride, gr. 15 (1 g.) t.i.d., by mouth, and also saline aperients if necessary. Avoid all sodium salts. Sometimes the intramuscular injection of a mercurial diuretic, one or two days before menstruation, is worth while in cases in which the above is insufficient.

If in spite of treatment the headaches continue, large doses of ergotamine tartrate by mouth (1 to 5 mg. initially, followed by 1 to 2 mg. every three or four hours) should be tried, keeping in mind its dangers if continued too long. It has recently been suggested that ergometrine works equally well, but I have no experience of this. Inhalations of pure oxygen are also said to give symptomatic relief in some cases.

If the headaches still persist, the patient will probably sooner or later raise the question of having the menopause induced artificially. If she does, it is contraindicated. As a last resort, however, and if the headache is very intense and associated with a calcified roof to the sella turcica, x-ray therapy to the pituitary gland might be considered, although it often has untoward side-effects, such as the development of obesity. Reference might be made to previous questions and answers on menstrual migraine which appeared in the *Journal* of Aug. 21, 1943 (p. 255), and Sept. 18, 1943 (p. 379).

First Aid for Cresol Burns

Q.—With the increase in the use of plastics, phenol and cresol burns are likely to become more frequent. During the process of manufacture of the "resin" employees are sometimes splashed by hot cresol. What is the best first-aid treatment?

A.—If the burning substances are not of a tarry nature, making them stick tightly to the skin, the burn should simply be put under the cold tap to relieve pain for the moment. Tap water has usually so few potential pathogens that it is safe. Stored normal saline is less safe unless one can be sure the bottle has never been opened since it was sterilized, but it has no real advantage over tap water. Hands and unsterilized linen should not be used for swabbing the burns. After they have been cooled with tap water they should be covered with a sterile cloth. Every factory should keep a number of such sterile cloths, wrapped in good stout paper and sterilized in an oven, for these emergencies. If the burn is too extensive and involves the trunk, so that it cannot readily be washed with tap water, pain should be controlled, if necessary, by morphine and the patient sent to hospital with the least possible delay.

Cirrhosis of the Liver

Q.—What is the modern treatment of Hanot's (hypertrophic) cirrhosis of the liver?

A.—The existence of a special hypertrophic type of cirrhosis (Hanot) is not generally accepted nowadays. Patients with chronic disease of the liver who have hepatic enlargement and persistent or recurrent jaundice usually prove to be suffering from subacute necrosis of the liver, and at necropsy they show a coarse or adenomatous type of cirrhosis with a variable amount of fatty infiltration. In cirrhosis due to alcoholism the liver may be large as a result of an increased content of fat. Jaundice may occur in all forms of subacute necrosis and cirrhosis; it usually signifies an increased activity or recrudescence of the disease process. A biliary type of cirrhosis should not be diagnosed in the absence of signs of obstruction or infection of the biliary passages. In the absence of these signs the patient should be treated as for subacute necrosis or cirrhosis. Possible causative factors, such as toxic drugs or chemicals, should be looked for. The main treatment is by diet. The fat intake should be reduced to a minimum, the protein intake moderately increased, and the bulk of the calories provided by carbohydrate. The vitamin intake should be raised: A, D, and K to compensate for the fat restriction, and the B complex for its therapeutic effect. Choline chloride has been recommended in this type of case. It is expensive, and the treatment is still experimental. It would be wise to begin with a dose of 1 g. t.i.d., and increase gradually up to, say, 4 g. q.d.s., preferably in solution after meals. If oedema or ascites appears, the salt intake should be reduced and one of the mercurial diuretics given. If jaundice is present the most effective remedy is probably rest in bed.

Sterility of Sulphonamides and Penicillin

Q.—I understand that drugs of the sulphonamide group require sterilization before use. A non-medical American druggist tells me this is not the case. I should be glad of chapter and verse to convince him that the sulphonamides do require sterilization, as they are not antiseptic in the true sense of the word. Is this also the case with penicillin?

A.—That a dry powder cannot be bactericidal is so self-evident a proposition that "chapter and verse" in support of it is hard

to seek. Whether the sulphonamides are antiseptic in the true sense of the word is a question which simply does not arise in this connection, because clearly whatever action they have can be exerted only in solution. The questioner's incredulous American friend is either under a strange misapprehension or really means that sulphonamides are so manufactured as to be bacteria-free, and so far that reason does not require to be sterilized. Contamination by dust or packing material, possibly containing tetanus spores, may nevertheless occur. The most accessible publication whereby he can be convinced of his error is *The Medical Use of Sulphonamides*, 2nd edition (M.R.C. War Memo. No. 10). The sterilization of sulphonamide powders is dealt with on the last page, which notes both the U.S. Pharmacopoeia tests for sterility and the work of Welch, Seacom, and Herwick (*J. Amer. med. Ass.*, 1942, 120, 361), who showed that sulphanilamide powder contaminated with tetanus spores produces tetanus in animals—i.e., so far from killing the spores, the drug does not even prevent their ultimate multiplication in the body.

Penicillin as supplied by the manufacturers is sterile, and solutions or other preparations made under satisfactory aseptic conditions should, therefore, not require further sterilization. If for any reason this should be thought necessary, it can be achieved only by filtration, since heat is destructive to penicillin. Some surgeons insist on the filtration of penicillin solutions to be used for intrathecal injection. Bacteria resistant to the action of penicillin, such as coliform organisms, will survive indefinitely in solutions of it.

Morphine in Coronary Thrombosis

Q.—Is it good practice to give 1/4 gr. (16 mg.) of morphine to relieve pain in coronary thrombosis or angina pectoris? Most G.P.s of experience must have had cases in which the patient died suddenly as the morphine was being absorbed.

A.—The injection of morphine is the correct treatment of coronary thrombosis: gr. 1/4 (16 mg.) should be given subcutaneously at once, and this dose repeated if relief from pain does not soon follow. For spasmodic or effort angina trinitrin is the treatment of choice: a tablet containing gr. 1/100 (0.65 mg.) is allowed to dissolve under the tongue, and one or two more may be taken if the pain is not relieved within a few minutes. Should the pain persist, morphine gr. 1/4 (16 mg.) is injected subcutaneously. The writer has not encountered the disaster to which reference is made, but in considering the possibility of cause and effect it must be remembered that death from ventricular fibrillation may occur abruptly at any time, and that this is most likely to happen in the earlier stages—the period during which morphine is likely to be administered. The remote possibility of such an accident should certainly not deter the physician from prescribing morphine for the relief of pain in coronary thrombosis or other forms of angina.

Treatment of Asymptomatic Congenital Syphilis

Q.—If a mentally defective child is found to have a positive blood Wassermann without any clinical evidence of syphilis, what treatment should it have? Would clinical or serological evidence of syphilis in the parents and/or siblings make any difference to the treatment prescribed?

A.—If a mentally defective child is found to have a persistently positive blood Wassermann reaction, and if, as a result, a diagnosis of asymptomatic congenital syphilis is made, the cerebrospinal fluid should be examined to exclude neurosyphilis. Assuming that the fluid is negative, treatment should consist of weekly injections of an arsenic compound—nearsphenamine if intravenous therapy is practicable, and sulpharsphenamine if the child is very young or has difficult veins—and a bismuth compound. These injections should be given concurrently in courses of ten of each, with rest intervals between courses of four to six weeks at first, increasing later. Treatment should extend over two years, or even longer if the serum reactions are not reversed, and thereafter the patient should be kept under observation for at least three years: dosage will depend on the age of the child and its tolerance to the drugs. Penicillin might be worth trying, but should be employed in addition to, not instead of, arsenic and bismuth. As yet there is little evidence available to show its value in such a condition. Clinical or serological evidence of syphilis in parents and/or siblings would serve to confirm the diagnosis, but would not affect the type or amount of treatment.

Adult Reactions to Diphtheria Immunization

Q.—In using A.P.T. in adults there have been some local reactions. What preparation should be used to immunize adults against diphtheria?

A.—Reactions to diphtheria prophylactic reagents are seen particularly in persons who give a pseudo-reaction to the Schick test: that is, those in whom a skin reaction occurs with the control material. This pseudo-reaction, which has been shown to correspond with the Moloney reaction (elicited by the subcutaneous injection of 0.1 c.c.m. of diluted formal toxoid), appears in persons who are partially immune and who therefore seem to be rather allergic to

diphtheria toxoid. In such individuals any one of the diphtheria antigens—toxoid, A.P.T., or T.A.F.—given in the usual dosage will elicit reactions of varying degrees of severity. Large-scale immunization of an adult population, or of older school-children, should therefore not be undertaken without preliminary Schick-testing. Pseudo-reactors are preferably not given any injections, as, being already partially immune, they are unlikely to develop diphtheria, and indeed the Schick test material itself is often sufficient to render them negative to further tests. If, however, preliminary Schick-testing cannot be done, the safest prophylactic for adults is T.A.F. An initial dose of 0.2 c.cm. should be given to all volunteers, and non-reactors should receive two further doses of 1 c.cm. at three to four week intervals. Reactors should not be given any further injections.

Senile Pruritus

Q.—Is complete rest in bed likely to prove beneficial to an intractable case of senile pruritus in a patient aged 80?

A.—Senile pruritus is unlikely to benefit from rest in bed, and might even be made worse, because the patient is able to give more attention to the itching skin.

Clicking Joints in a Baby

Q.—A mother states that she can hear the joints of the back cracking in her 14-months child. I have been unable to find any abnormality. Should I refer the case to an orthopaedic surgeon?

A.—The present writer in an extensive orthopaedic practice has seen a few small infants who have had queer clicking joints. The phenomenon appears to be without any great significance, for these symptoms seem to disappear. Unless there is any clear evidence of physical disturbance one would suggest leaving the problem and reviewing it from time to time. If the mother continues to be distressed by the peculiarities which the child presents it would certainly be worth while seeking confirmatory advice.

INCOME TAX

Assistant Provided with Furnished House

S. B. employs two assistants, each of whom has the use of a free furnished house; he pays income tax on the rental value and also owners' and tenants' rates.

* S. B. can deduct as an expense of the practice the amounts on which he bears income tax in respect of the properties—as he could deduct the rent if he rented them. He can also deduct the payments he makes for repairs, rates, maintenance of furniture, insurance, and other current expenses incurred on the properties.

Appointment: Travelling Expenses

I. W. is a medical officer whose duties involve a good deal of travelling. As he is compelled to live out he receives an allowance of £100 per annum. When he goes away he receives a subsistence allowance of 14s. a day for the first 7 days and 9s. a day for succeeding days. These rates, it is suggested, are too low, as they compare unfavourably with the 20s. a day which would be paid as subsistence if he were living in a hospital. Can he claim anything for income-tax purposes in view of his low subsistence rates?

* The governing principle is that a claim can be made only for expenses incurred "wholly, exclusively, and necessarily in the performance of the duties of the office." What I. W. would have to do to succeed in his claim would be to satisfy the local inspector of taxes (or on appeal from his decision a board of commissioners) that the cost of his visits outside his residential radius was necessarily greater than the amounts allowed him by his employer; and in measuring that cost it is to be presumed that any savings in respect of food, etc., at his residence would be taken into account. Obviously his prospects of success depend on his particular circumstances, but proof of the correctness of his claim would be difficult.

Fluctuation in Income

E. T. first became liable to income tax for 1944-5, but since April, 1945, owing to illness, has earned only £16. Can the two years be combined or averaged?

* No; each financial year must be treated as an isolated unit.

Appointment: Car Expense

H. S. had retired and subsequently accepted an appointment involving attendance at a board held 12 miles distant from his residence. Can he claim to deduct the expense of travelling to and from the board?

* No. In the circumstances the expense is incurred not "in performing the duties of the office" but antecedently in order that H. S. may be in a position to commence performing his duties. The case is somewhat similar to that of an employee who lives in the suburbs and travels to his employment.

LETTERS, NOTES, ETC.

Medical Books for Yugoslavia

Mr. HAROLD EDWARDS (King's College Hospital, Denmark Hill S.E.5) writes: The doctors of Yugoslavia are very short of modern British medical literature, having received practically none since the war started. They are most anxious to make good this shortage and on a recent visit to Belgrade I promised those who asked me—and they were many—to do what I could to help. If any of your readers can spare any standard works or series of periodicals (odd ones or twos are of little value) published in the United Kingdom since September, 1939, and would send them to me I will undertake to have them forwarded to Yugoslavia through military channels by kind agreement of the D.G.A.M.S., Sir Alexander Hood. A gift of this kind would be appreciated very much, and may help to increase the friendship and good will between the two countries. It is suggested that contributors write inside each volume: "The gift of (name and address)." This may lead to the development of individual friendships.

Coccygodynia

Dr. T. ASTLEY COOPER (Birmingham) writes: I wonder if any other practitioner has had similar experience to mine. I have had to deal lately with a rather interesting case of coccygodynia. The man is about 40 years of age and complains that from time to time he awakes during the night with a vague sensation of discomfort in the region of the sacrum. This discomfort gradually develops into a most intense neuralgic pain in the region of the coccyx. Nothing will relieve the pain until, after pacing the bedroom for some time a small amount of flatus is passed. The pain then subsides, but is so severe at the time that it leaves him quite exhausted. Another interesting feature is that it will frequently occur after sexual intercourse. Physical examination is quite negative and there is nothing to be discovered per rectum. These attacks have occurred at intervals since childhood. The only information I can get is that it is coccygodynia—which is obvious; but no help as to the possible cause of this pain or suggestions regarding its prevention. I presume it is due to pressure, but what the mechanism of this is remains rather a mystery.

Abortion and the Birth Rate

Dr. B. DUNLOP (Binfield, Berks) writes: Your welcome article (Dec. 29, p. 926) about the book *Britain and her Birth-rate* contains a long quotation from it which asks: "Is the sad truth to-day that children are distributed in inverse ratio to knowledge and the ability and desire to assimilate facts?" and which later says: "There is no reason to suppose that legislation will alter this pattern fundamentally." I submit that legislation could, however, alter this pattern fundamentally by relaxing the abortion law sufficiently to enable women to avoid having more children than they desire—a law which is an outstanding infringement on liberty.

Hospital Service Plan

Dr. S. M. R. THOMSON (London, E.13) writes: The letter by Sir Hugh Lett and Dr. W. Russell Brain on the London Hospital Service Plan (Dec. 29, p. 936) brings to the notice of the medical profession a very useful scheme. While it is a good plan for the general public, I would recommend it also to doctors and their dependants. The fees for hospital and for medical and surgical in-patient treatment are paid direct to the hospital and to the surgeon or physician who has given the necessary treatment. If a doctor or his dependant has been the patient this simplifies the question of gifts for service rendered and puts the whole matter on a business-like basis, more satisfactory to all concerned.

Nylon for Buried Sutures

Dr. T. RUSSELL STEVENS (Dorchester) writes: May I assure Mr. H. A. Haxton (Jan. 12, p. 66) that I will try his method of tying knots with nylon. Our case for nylon is strengthened by the two letters by Mr. H. I. Deitch and Mr. H. J. McCurrah, immediately following his letter. I would suggest to all those who are champions of catgut that there is no argument about the properties of nylon, such as has been raging about catgut. *Verb. sap.*

Nodules at Site of A.P.T. Injection

Dr. M. F. McDONNELL (Northfleet, Kent) writes: With reference to the answer given to the query about nodules forming after immunization with A.P.T. (Dec. 22, 1945, p. 908), we find that the following procedure eliminates the lump: (1) insert needle vertically and deep into upper deltoid muscle; (2) withdraw needle and gently massage the muscle at site of injection.

Correction

We regret an error on page 3 of the *Journal* of Jan. 5. "A rapid transfusion of a pint (473 c.cm.) of blood" is wrong. The pint to be transfused should have been an Imperial pint (568 c.cm.) and not a United States Apothecaries' pint (473 c.cm.).

BRITISH MEDICAL JOURNAL

LONDON SATURDAY FEBRUARY 9 1946

EFFECT OF A DAILY VITAMIN SUPPLEMENT ON THE HEALTH AND DEVELOPMENT OF CHILDREN

BY

C. R. BRANSBY, Ph.D. J. L. BURN, M.D., D.H., D.P.H.
H. E. MAGEE, M.B., D.Sc.

AND

The late D. M. MacKECKNIE, M.B., D.P.H.

The purpose of the investigation was to examine the effect of a daily supplement of vitamins in capsule form on the health and development of children living at home and attending day schools in Stoke-on-Trent and Salford. A similar investigation (Bransby *et al.*, 1944) had been made previously, and the present study was in the nature of a confirmatory test.

Literature.—The following review of the literature on the effects of vitamin supplements is limited to those studies in which the supplement was additional to the normal diet, and consequently excludes investigations in which the experimental subjects had diets with restricted vitamin intakes. Further, it does not include the study by Frankau (1943) in which a large vitamin dose was given for a few days as the results may have been due to the pharmacological effect of the vitamins in the supplement. The studies included in this review can broadly be divided into two—those concerned specifically with infections of the upper respiratory passages and those dealing with a wider range of conditions. The former have been reviewed by Keefer (1943), who concluded that the available evidence indicates that vitamin therapy has no effect on colds. The studies dealing with a wider range of conditions are summarized in Table I. The most marked effect of the vitamin supplements was obtained by Borsook (1945) on factory workers, but it must be pointed out that the daily dosages were about 10 times in excess of requirements. The improvements obtained may have been due to a pharmacological action, and the test does not throw light on the desirability or otherwise of the continued administration of such tonics. The results of the other tests are contradictory, and show that the vitamin supplements had no consistent effects.

Method.—The test was made on 1,620 children, aged 5 to 14 years attending elementary or secondary schools. In both areas Stoke and Salford the children were divided at random into two groups, one of which received one vitamin capsule daily, the other a placebo daily. Each vitamin capsule contained vitamin A, 4,000 i.u., vitamin B₁, 1 mg., riboflavin 2 mg., nicotinamide, 20 mg., ascorbic acid, 50 mg., vitamin D, 600 i.u. All practicable precautions were taken by the teachers to ensure that the capsules were eaten. The test started at the beginning of 1943 and ran in each locality for one year. Medical, dental, and anthropometric data were collected in Stoke three times during the experimental year (namely, at the beginning, three months subsequently, and at the end) and in Salford twice (at the beginning and at the end). In both Stoke and Salford records were kept for each child of the extent of and reasons for, absence from school. Other data collected for the experimental subjects were the number of children in the families to which they belonged, their home conditions, the type of school to which they went, and whether they took school milk or dinners, free or paid for. In Salford, data were collected on the economic conditions of the families of the experimental subjects. In Stoke the children performed dynamometer and hanging bar tests, and in Salford the hearing was tested by means of the audiometer.

Dietary Data.—As a part of the investigation dietary data were collected from a representative sample of the experimental subjects to ascertain the levels of the vitamin intakes from the ordinary diets. Dietary surveys in Stoke and Salford were made both in Aug./Sept., 1943, and in March, 1944, and the results have already been reported (Bransby and Wagner, 1945). It was found that on the average the intakes of nutrients

except calcium, were adequate or nearly so according to the League of Nations standards. The actual average daily vitamin intakes found in each survey were of the order of vitamin A, 3,000–4,000 i.u., vitamin B₁, 1–1½ mg., ascorbic acid 35–45 mg. The ascorbic acid intake found in March 1944 was raised above the general average for that time of the year owing to a chance distribution of oranges, and it was calculated that without the oranges the average intake would have been of the order of 20–25 mg. per head daily. Although the average intakes of nutrients except calcium, were generally sufficient, many individual children had intakes which were poor compared with the League of Nations standards. A paper by G. A. Jenkins dealing with the ascorbic acid content of the cooked vegetable eaten by children will shortly be published in the Journal.

Analysis of Data.—Recognized statistical methods were used for comparing the effect of the vitamin and placebo capsules. The standard errors of the initial height and weight, dynamometer pull, barium fluoride potential and audiotape data, as well as the standard errors of the height and weight increase and the changes in other factors were calculated by the t-test method. For the clinical and dental data, account was taken of both the incidence and the severity of the conditions which were included in the examinations. Inspection and analysis of sections of the clinical and dental data showed that the distribution of the various grades of severity among the children could be regarded as a Poisson distribution, and the standard errors of the initial scores and score changes were calculated accordingly. For most of the comparisons the data for boys and girls were treated separately in the three age groups 5–7 years, 8–10 years, and 11 years and over. Considerations of space prevent the inclusion of all but a few of the tables of results.

One of the purposes of collecting data on the number of children in the family (classified 1 or 2, 3, 4 or more), home conditions (graded good, fair, or poor) and economic conditions (graded good, fair, or poor) to which the experimental subjects belonged was to enable the experimental data to be broken down into sub-groups according to those factors. This meant that the effect could be assessed of the vitamin supplement on children living under poor conditions and consequently likely to be receiving a deficient diet. The factors by which such breakdowns were made were the general nutritional grade at the beginning of the experimental period, the number of children in the family, the home conditions, the economic conditions, the type of school which the child attended, and whether the child had milk or dinner at school free or paid for. The children were classified by single factors, such as economic conditions, and also by multiple factors, such as both economic conditions and the number of children in the family. The numbers in some of the resulting groups were small, and the Stoke and Salford data were, where possible, considered together. The resulting tables were examined in detail, and

TABLE I.—*Summarized Results of Studies on the Feeding of Vitamin Supplements*

Worker	Subjects	No.	Duration (Months)	Daily Vitamin Supplement						Effect of Vitamin Supplement
				A (i.u.)	B ₁ (mg.)	B ₂ (mg.)	Niacin (mg.)	Ascorbic Acid (mg.)	D (i.u.)	
Borsook (1945)	Men	528	12	50,000	10	10	100	250	800 (a)	Improved output due to better work and reduced absenteeism
Bransby <i>et al.</i> (1944)	Children	1,040	9	4,000	1	2	20	50	600	No effect: growth, strength, clinical or dental condition, absenteeism. Improvement in endurance and fatigue potential
" "	Men	214	9	4,000	1	2	20	50	600	No effect: weight, haemoglobin, blood pressure, absenteeism, output
Glazebrook and Thomson (1942)	Youths	1,500	6					50		No effect: incidence of colds and tonsillitis. Reduced duration of tonsillitis and incidence of rheumatism and pneumonia
Harper <i>et al.</i> (1943)	Cadets	69	5	6,000				50	1,000	No effect: growth, chest. Improved vital capacity, breath-holding, endurance, pulse rate, susceptibility to minor ailments
Jenkins and Yudkin (1943)	Children	178	12	5,000	1			25	500	No effect: pulse rate, vital capacity, breath-holding, endurance
Johnson <i>et al.</i> (1945)	Men	8	2					75		No effect: general well-being, vigour and efficiency in work
Keys and Henschel (1942)	Soldiers	26	10 (c)	See footnote (d)						No effect, either in brief, extreme, or prolonged severe exercise or semi-starvation, on muscular ability, endurance, resistance to fatigue, recovery from exertion
Mangold (1945)	Children	38	5		2					No effect: height, weight, alertness
Raffin and Cayer (1944)	Students	200	1	7,500	3	4.5	30	82	600 (b)	No effect: appetite, energy, health, weight, indigestion, abdominal pain, diarrhoea, nausea, vomiting
Sutherland (1934)	Children	575	6	A and D equiv. to 1 oz. (28.4 c.cm.) of cod-liver oil						Possible slight effect on growth, none or susceptibility to infection or resistance to established disease

" 3 ..	17	100	20	10	10	200
" 4 ..	—	—	—	—	100	—

conclusions based on them have been referred to where desirable. It is hoped to publish a separate paper dealing with health conditions according to economic and social factors.

Comparison of Experimental Groups

At Beginning of Test.—Table II shows the findings for the various experimental groups in Stoke and Salford at the beginning of the test. In Stoke there were no significant differences between the vitamin groups and their corresponding control groups in weight, height, pull, bar-time, and fatigue potential. In Salford there were no significant differences in weight, height, or audiometer scores, except that the girls aged 11–13 years in the vitamin group were heavier and taller than the corresponding group. The latter was an unexpected result, as the children were randomly selected.

Over the Test Periods.—Table II shows the increments and the differences between the increments of the vitamin and control groups over the test periods. None of the differences between the vitamin groups and their corresponding control groups is significant, except that the weight increments of boys aged 8–10 years in Stoke receiving the vitamin supplement were greater at the second and third examinations than those for the corresponding control boys receiving the placebo, and that the improvement in hanging-bar time of boys aged 11–13 years was greater in Stoke among those receiving the placebo than among those receiving the vitamins. Considering the large number of differences which are not significant and the lack of consistency of the results, little importance can be attached to these two significant differences. There is some consistency in the results for both weight gain and dynamometric pull in Stoke, but the differences are small and probably unimportant.

The data were further analysed to compare the changes in the vitamin and control groups according to the social and economic factors referred to above. No consistent differences between

the vitamin and control groups could be discovered when the children were classified according to a single factor or a number of factors. It therefore seems that the vitamin capsules had no discernible objective effects on growth, pull, bar-time, fatigue potential, or hearing compared with the placebo.

Effect on Clinical Conditions

The following clinical conditions were recorded at the medical examinations made during the test: state of nutrition (good, fair, or poor), round shoulders, pot-belly, lordosis, winged scapula, knock-knees, bow-legs, deformed chest, pallor of face, physique, obesity, enlarged tonsils, chest rales and cough, ear discharge, goitre, angular stomatitis, cheilosis, inflamed gums, colour of mucous membrane, nasal discharge, mouth-breathing, styes, blepharitis, simple conjunctivitis, phlyctenular conjunctivitis, longitudinal and transverse ridging of nails, white spots on nails, nails bitten, brittle nails, coarse and dry hair, impetigo, boils, chilblains, acne, seborrhoea, follicular keratosis, dryness of the skin. Each of the clinical conditions was graded at each examination 0, 1, 2, 3, or 4, according to its presence and severity.

In Stoke the data for boys and girls were analysed separately. In Salford the data for boys and girls were combined. Because of the large number of clinical conditions for which data were obtained and the number of groups into which the children were divided, tests for the significance of the differences between the vitamin and the control groups were made at the level of twice and also of three times the standard error.

In Stoke, on the basis of a difference being significant at twice its standard error, the vitamin supplements brought about an improvement of chilblains in boys and nail-biting in girls at the second and third examinations. Nose discharge decreased in boys at the second and in girls at the third examination. Rales diminished in girls in the first period. On the

decided to treat the worst caries cases. Therefore, in the analysis, the children were grouped into those who did not require treatment, those who received treatment, and those who required but refused it. The data of the three groups were analysed separately and together. This complication did not apply to the other tooth and gum conditions under investigation. For both Stoke and Salford the data of boys and girls were analysed separately, for the age ranges 5-7 years, 8-10 years, and 11-13 years. The average scores for each of the conditions were, with but a few exceptions, the same for the vitamin groups and their respective control groups. For both Stoke and Salford no discernible effect of the vitamin supplement was found on caries, mottling, general gum tone, or tartar. A significant effect of the vitamin capsules on the incidence of gingivitis is indicated, and the figures for that condition are given in Table IV.

TABLE IV—(a) Initial Scores for Gingivitis at the Beginning of the Test. (The scores relate to the total gingivitis intensity for the regions 51112)

* Difference is significant. V = Vitamin group. C = Control group.

There were no differences in the initial gingivitis scores between the vitamin groups and their respective controls apart from that in Stoke the initial scores among girls aged 5-7 years and those aged 11-13 years were greater in the vitamin groups than in their respective control groups. Over the test period of one year the improvement in gingivitis was greater in the vitamin groups in 5 out of 6 groups in Stoke, of which two of the differences are significant. Generally, the differences are of such a size as to be noteworthy. It must be observed, however, that these two significant differences occur in favour of vitamin groups which initially had a significantly higher incidence of gingivitis than did their controls. Over the first three months of the Stoke study the improvement was in favour of the vitamin group in 6 out of 6 groups, but over the last nine months there were no consistent differences between the vitamin and the control groups. These findings suggest that the vitamin supplement had a beneficial effect on gingivitis, particularly during the first three months of medication. The supplement had no significant or consistent effect on gingivitis in Salford. It should be noted that, generally, the initial gingivitis scores were higher in Stoke than in Salford.

The vitamin capsules contained ascorbic acid and nicotinamide, both of which have been claimed to have a beneficial effect on gingivitis (King, 1943, 1945a, 1945b; King, Franchlyn, and Allen, 1944; Campbell and Cook, 1942, 1945). During the period of the present test, groups of children in Salford, in a parallel investigation, received a supplement of 50 mg. of ascorbic acid daily, and another group was studied which received no supplement or placebo of any kind. These groups

were not strictly comparable with the present experimental groups, as the children in them were chosen from different schools, but they provide data on gingivitis which can be considered in conjunction with those of the vitamin and placebo groups. These data are given in Table V.

TABLE V.—Average Initial Gingivitis Scores, and Changes during the Test Period of Groups of Children Receiving a Supplement of Ascorbic Acid or No Supplement or Placebo of any Kind

				8-10 Years	11-13 Years
Groups receiving Ascorbic Acid

Initial score	2.83*	2.73	
Change	-1.88*	-0.03	
Groups receiving No Supplement or Placebo					
Girls:					
Number	—	36	
Initial score	—	1.33	
Change	—	-0.42	

* Significantly different from corresponding placebo group

For boys aged 8-10 years and 11-13 years neither the initial scores nor the changes were significantly different from those of the corresponding Salford placebo groups. For girls aged 8-10 years the initial score was higher and the improvement greater for the vitamin group than for its appropriate placebo group. There was no placebo group corresponding to the girls aged 11-13 years receiving ascorbic acid, but there was a similar group receiving neither supplement nor placebo. Although the initial score of the former was significantly greater than that of the latter, the changes were not significantly different. It must be observed that the improvement due to the ascorbic acid supplement in the former group was negligible. The above data suggest that the supplement of ascorbic acid alone had no beneficial effect on gingivitis. From this it might be inferred that the ascorbic acid in the vitamin capsule was not responsible for the improvement in gingivitis, although there is the possibility that the improvement was due to combination of ascorbic acid with other ingredients of the vitamin capsule.

Effect on Absence from School

All absences from school were classified into the following categories of complaints: respiratory; skin; ear, nose, and throat; gastro-intestinal; eyes; infectious; unspecified illness; injuries; no illness. Information on absenteeism was checked by health visitors or school nurses at the homes of the children who had been absent from school. Table VI shows:

TABLE VI.—Average Number of Days' Absence per Child from Various Causes during the Experimental Periods

EFFECT OF BLAST ON THE HUMAN EAR

BY

F. BOYES KORKIS, D.L.O.Eng., F.R.C.S.Ed.

Major, N.Z.M.C.

The effects which follow exposure of the human auditory apparatus to blast waves receive but scant attention in current textbooks. It is the aim of this paper to present, in a general way, a composite picture of the results of injury to ears by the detonation of near-by explosives.

Blast lesions of the ears are frequently seen by medical officers on active service and, with increasing demobilization, civilian medical services will meet this problem often. It is not possible to exclude the superadded effects of noise, which of itself is capable of producing an inner-ear type of deafness. All soldiers in the field are exposed to battle noises, but only those cases of deafness which have followed acoustic trauma from blast waves are included in this article. The opinions expressed are the personal ones of an Army otologist who has seen large numbers of cases of blast deafness in base hospitals in the Middle East and in Italy.

Incidence

In 1,000 consecutive in-patient battle casualty admissions 31 (3.1%) had deafness attributable to blast. Of these, approximately 40% had associated wounds, the remainder being admitted to hospital solely for the aural lesion. Analysis of these 31 cases showed that about half had a blast rupture of a drum, but, from an experience of a very large group of cases over a three-year period, this figure did not represent the true relation of rupture to non-rupture cases, for the following reasons: (1) Cases of ruptured drums were usually evacuated from forward areas to the base, whereas non-rupture cases were held at forward medical units. (2) Failure of medical officers to send for specialist investigation patients with normal drums but with blast deafness. (3) At out-patient clinics the ratio of blast cases with rupture to those without rupture was 1:2. (4) Failure of individuals to report deafness to their medical officers.

We may assume, therefore, that the greater number of blast-deafness cases are not associated with a break in the continuity of the tympanic membrane. In these, noise may play an associated part in the production of the deafness, but in all of the cases reviewed above a definite history of blast injury was obtained.

Aetiology

The aural lesions are produced by the direct traumatic effect of a blast wave on the structures comprising the middle or the inner ear, or both combined; rarely by the indirect method of

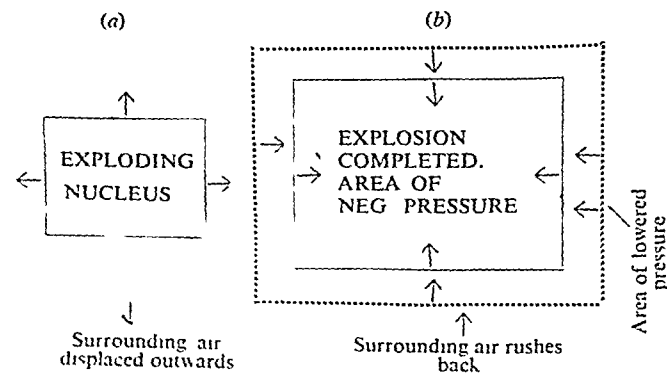

FIG 1—(a) Production of primary wave: area of negative pressure being produced in the vicinity of the blast wave of the explosion (b) Production of secondary wave. Air rushes inwards to equalize the pressure

basal skull fracture involving the petrous portion of the temporal bone.

There are two phases to the so-called blast wave—primary and secondary—the mode of production of each being explained in Fig 1. Either the primary or the secondary wave is capable

of producing aural damage—the first by its percussion effect and the second by a suction action. It is not possible to say which is the most important factor. The ear may be damaged by a single wave of great amplitude, or repeated traumatization may result in a demonstrable degree of deafness, the drum remaining intact.

The part played by noise in the production of deafness has already been mentioned. "Boiler-maker's deafness" may be cited as an example in which long-continued noise produces a degeneration of parts of the inner ear, ultimately resulting in an inner-ear type of deafness, the drum remaining intact. Such a condition is insidious in onset, and is not related to sudden acoustic trauma such as is produced by a blast wave. Undoubtedly many soldiers suffer from a nerve-type deafness which has as the aetiological factor "battle noise." Others are seen with similar clinical findings, but the onset is related to the effects of a near-by explosion that has caused a sudden deafness, which may pass off in a few days, only to recur when the ears are again blasted. Such a deafness I consider to be a true blast deafness, the wave having damaged inner-ear structures.

Noise may play an associated part in the production of lesions of the inner ear, but in these "blast cases" it is not the major factor. "Battle-noise" deafness in which no true blast element could be ascertained is not included in this paper.

Classification of Lesions

First Group: Fractured Skull.—A fracture of the base of the skull involving the petrous portion of the temporal bone causes a traumatic deafness akin to that seen in civilian practice. Haemorrhage into and disorganization of the inner ear result, producing a deafness of inner-ear type. This injury is of rare occurrence, and leads to a severe degree of disability.

Second Group: Lesions of the Middle Ear.—Blast rupture involves the pars tensa of the drum, is of any size or shape, and occurs in any quadrant. Haemorrhage into the middle-ear cleft or into the external canal, via the perforation, results. *Blast contusion* of the tympanic membrane and haemo-

TABLE I

Symptoms	Middle-ear Type	Inner-ear Type
Deafness	Onset sudden after a blast injury Usually single exposure Severe degree at onset Usually unilateral May be bilateral at onset, with unilateral lesion Course: often sudden improvement after quiescent period Increase if otorrhoea supervenes Residual deafness may persist	Onset follows definite "blast." Cf. noise deafness—insidious onset Single, or multiple Slight or severe—progresses if trauma repeated Usually bilateral and of equal degree in the two ears Slow, gradual improvement or no recovery No increase if no re-exposure
Tinnitus	Occurs in 70% of cases Unilateral. May be bilateral at onset Gradually diminishes. May persist	90% of cases Often bilateral Often persists. Apt to be permanent. Often leading symptom
Vertigo	66% of cases. Duration short: few minutes to a few hours Rarely over 24 hours	Not usual
Otalgia	50% cases at onset. Recurrence or exacerbation with subsequent infection	Not usual
Headache	50% cases Frontal or occipital. Lasts up to 3 days; usually only a few hours	Sometimes; frontal or occipital. If present may persist for weeks
Bleeding	From external meatus in 25% cases May be mixed with C.S.F. if basal fracture	Not found
Whistling of air through the perforation	Not common: 10% of cases	Not found
Aural discharge	Usually on 2nd to 5th day. May occur at any period if perforation remains open. Serous, seropurulent, or purulent. Copious, moderate, or small in quantity. Often sero-sanguineous at onset	Not present unless related otitis media externa occurs

Treatment

Prophylaxis.—The wearing of plugs in the external meatuses might help to lower the incidence of rupture, but it is difficult to find a suitable material which will be firm enough and yet will allow a reasonable standard of hearing. Such a measure is therefore impracticable in modern warfare. A regular six-monthly check of those exposed to the effects of blast offers the best hope of reducing the incidence of severe nerve deafness. Any showing deafness could be removed from the source of trauma before high-grade disability was established. Those possessing healed ruptured drums should be protected from further blast damage in a similar manner.

Uninfected Blast Ruptures.—Since the use of anesthetic aural drops increases the likelihood of infection these ears should be left strictly alone. These patients are warned that it is dangerous to allow water to enter their ears, and swimming is prohibited. Should a coryza develop, forcible blowing of the nose, with the nostrils occluded, is contraindicated. Inhalations of mentholated steam are advised. The prophylactic use of chemotherapy to reduce the incidence of infection is of doubtful help. If employed a full course should be given.

Infected Blast Ruptures.—Treatment should be along the lines already indicated. The need for admission to hospital and for a thorough local toilet is again stressed.

Nerve Deafness.—Little active treatment is possible. Rest from the field, reassurance, and, if tinnitus is severe, a 14-days course of phenobarbitone are employed. Removal from the source of injury is essential.

Prognosis

It is difficult at an early examination to say which ruptures will heal and which will not. In general, extensive gaps in the tympanic membrane are unlikely to close; moderate-sized lesions, involving a third of the pars tensa, have a fair chance of doing so; while small perforations are likely to heal spontaneously, providing there is no complicating factor such as persistent infection. If the edges of the rupture show vascularization a fortnight after the injury, the repair is taking place normally. If no such red edge is seen at the end of six weeks there is little chance of closure. A perforation which has shown no change in three months will not heal spontaneously. The presence of otitis media delays healing until the infection has been controlled, but thereafter the reparative processes often proceed with surprising rapidity. One wonders whether the onset of an otitis is not, on occasion, helpful, the increased local vascularity stimulating fibroblastic reaction. On the other hand, persistent pus is very likely the forerunner of permanent perforation.

Recovery of hearing proceeds at varying rates. Ruptures which heal, leaving little, if any, visible scar, sometimes recover full acuity of hearing to the human voice, providing there is no permanent associated nerve deafness. Fork tests, and the audiometer, usually reveal gaps in the lower-tone register, however. Uninfected, unhealed lesions also, under the same conditions, often recover almost completely. Some cases show a residual middle-ear or "mixed" deafness at the end of six months, and such deafness is likely to be permanent.

Otitis media lowers the hearing until the tissues have recovered from the inflammatory reaction, and may result in a permanent deterioration of this faculty. Therefore, in blast ruptures considerable improvement of hearing is probable, but prognosis as to full recovery should be guarded. It is the degree of associated cochlear deafness that often determines the final acuity of hearing in "mixed" deafness. In nerve deafness of blast origin a guarded prognosis should be given. Many cases recover completely when judged by the spoken voice, but the upper-frequency forks (2,048 and 4,096 D.V.s per second) and the audiometer usually reveal a permanent depression at those frequencies—in most cases developing rapidly up to a certain point, then slowly or no further; a few continue to have a high-grade inner-ear deafness. Any deafness remaining at the end of six months is likely to be permanent.

Tinnitus is apt to be a persistent and annoying symptom in cases of labyrinth deafness.

The Future

With the termination of hostilities many soldiers will return to civilian life with a legacy of their service in the shape of deafness, with or without an otorrhoea. Such a disability is pensionable. Others as they approach the age of 40 years—the age at which idiopathic nerve deafness starts—will become deaf, and may apply for compensation on the grounds of their war service. Such deafness is unrelated to their service and is not pensionable. Unfortunately, the clinical pictures and the audiometric records of blast nerve deafness and of senile deafness are similar. In the differential diagnosis stress will be laid on the history and on the age of the patient.

The routine audiometric recording of the hearing of Service men under the age of 40, prior to their discharge, is urged. A permanent record of the state of the hearing before the onset of possible senile deafness would be available, and this would be of inestimable value to the otologist in assessing this difficult type of case at a later period.

Summary

An outline of an Army otologist's views on the incidence, aetiology, and types of blast injuries to the ears is given.

The high percentage of associated cochlear trauma in blast ruptures is stressed.

Infection after rupture occurs in approximately half the cases, and usually begins within four days of injury.

A half-yearly otological examination of soldiers, to determine the presence or absence of blast deafness, is indicated.

Prognosis is doubtful, and should be guarded. Residual deafness may remain.

Routine audiometry upon demobilization is advocated.

Acknowledgment is made to Brig. H. S. Kendrick, NZM.C., D.M.S., 2 NZ.E.F., for permission to undertake this investigation; and to Sgt. B. E. Conway and Cpl. O. R. Riley, of the NZM.C., for invaluable assistance in record-keeping.

THE HIPPURIC ACID TEST IN PREGNANCY

BY

W. LAQUEUR, M.D. Basle

Pathologist

AND

HIKMET OVACIK, M.D. Istanbul

Resident Assistant

Second Clinic of Obstetrics and Gynaecology, Medical Faculty,
University of Istanbul

Since the hippuric acid test was introduced by Quick (1935) for clinical purposes many investigations have been published stressing its value in the diagnosis of liver impairment. The importance of the test lies, according to Rennie (1942), Higgins *et al.* (1944), and others, in the detection of a general liver dysfunction: rather than as an aid in the differential diagnosis of liver diseases. Its delicacy as a measure of liver efficiency made its use attractive for our purpose, as it might show more conclusively whether or not there exists a real deficiency in the liver metabolism due to pregnancy. The hippuric acid test has been applied to pregnant women previously, so far as we know, only by Neuweiler (1939), who investigated the hippuric acid excretion during pregnancy and the puerperium. He found a generally low output in pregnancy, with a very wide range.

This investigation has been made in our antenatal clinic on 50 pregnant women during the last trimester. No particular selection was made, except that women with the slightest signs of oedema, albuminuria, or hypertension were excluded. Twenty women attending the out-patient department with general gynaecological complaints were taken as controls.

Methods

In order to avoid the often-reported nausea and vomiting after oral application of sodium benzoate, and also a wait of four hours, we used the intravenous modification of the Quick test as described by Quick, H. Ottenstein, and Weltchek (1938).

FIG. 3.—Case 2. "Drop to the right" by both air and bone conduction. Nerve deafness of blast origin.

Remarks on Case 2.—Man aged 36. Blast deafness; drums normal—intact and mobile. Weber: No lateralization. Rinne: Positive R. and L. Fork at 4,096 not heard by B.C. on either side.

"Mixed" deafness, as the name implies, is a combination of the two types, when both the middle and the inner ears have suffered. The fork findings are variable, depending on which structure suffers the greater damage, and may change as recovery occurs in one or the other.

In a series of 96 blast-ruptured drums it was shown that 80 (83%) had a demonstrable nerve deafness in addition to the middle-ear deafness. In an average type of case, with a unilateral rupture and "mixed" deafness, the common findings are:

1. Loss by air conduction is greater than that by bone conduction; negative Rinne; Weber lateralizes to ruptured side.
2. Moderate loss of a few seconds by bone conduction with a 256 fork tested against a normal ear.
3. Both lower and upper tones are affected to a greater or lesser extent. The lower-tone limit is raised (patient unable to hear fork 16 D.V.s per second by air conduction). The upper tones are depressed, especially at the frequencies of 4,096 and 2,048 D.V.s per second, marked loss being shown to these forks by bone conduction.
4. The unruptured drum often shows the fork reactions of a nerve deafness.

FIG. 4.—Case 3. "Mixed" deafness; both A.C. and B.C. affected—high and low frequencies by A.C. Note drop in high frequencies by B.C. The most common type of audiogram in blast ruptures, 83% of deafness being of "mixed" type.

Remarks on Case 3.—Gunner aged 21. Blast from blow-back of breech of 25-pdr. on May 29, 1944, causing deafness and tinnitus—bilateral. R. ear towards breech. Personal and family history negative. June 6: Blood-clot in R. canal. Uninfected reniform perforation of postero-inferior quadrants, right; small antero-inferior blast perforation just healed, left. Weber to right. Rinne: Negative R., positive L. 16 fork not heard by A.C. right; 4,096 fork not heard by A.C. or B.C. right. Loss to 256 fork equals 5 secs.

5. Audiometry shows "the horizontal drop"—see Fig. 4—or the inverted V type of curve, in which the hearing loss is least in the centre of the frequency scale—512 or 1,024 cycles per second.

6. If the rupture heals and middle-ear hearing returns, nerve type deafness may remain. Nerve deafness may improve, leaving a middle-ear deafness, but this change is not so common as the first type of reversal mentioned.

Infection of the Middle-ear Cleft

Incidence.—75 out of 152 (49%) consecutive cases of blast rupture gave the history or had the signs of otitis media following upon the injury.

Relation to Interference.—By interference is meant the instillation of fluids or solids into the external meatus, inadvertently (swimming) or therapeutically (syndring, drops). In the above series 23 (15.1%) had interference, and 18 of these developed a subsequent infection—an incidence rate of 78%. Interference is thus a positive factor in the production of infection of the middle-ear cleft.

Time of Onset.—Of the above series 62.7% developed otitis media within four days of the blast rupture. In the late cases—that is, those that occur after 8 days—a very positive cause for the production of the infection is usually found—e.g., acute nasopharyngeal infection, late interference, or pre-existent chronic nasopharyngeal sepsis.

Bacteriology.—The infection in those cases reaching hospital is usually a mixed one, with streptococci, staphylococci, or pneumococci, associated with *Ps. pyocyanea*, *B. proteus*, or diphtheroids.

Symptoms and Signs.—Pain in the ear and an increased deafness precede the otorrhoea. The typical picture of acute otitis media presents itself, the traumatic perforation standing out clearly in some cases, while in others it is masked by debris or by oedematous middle-ear mucosa.

Complications.—Chronic otitis media is the commonest sequel, but is uncommon if patients are brought under aural supervision in the early stages. The usual causes of failure to cure the acute condition include neglect of efficient aural toilet, failure to eradicate chronic nasopharyngeal foci surgically, failure to deal with subacute mastoiditis when the otorrhoea persists over five weeks, and the use of chemotherapy to the exclusion of local toilet and surgery where such are indicated. Acute mastoiditis is uncommon, probably because of the excellent drainage afforded by the rent in the tympanic membrane. Subacute mastoiditis, however, is common, and unless the condition is treated many cases of chronic otorrhoea result. One case of meningitis (pneumococcal) has been seen, this being secondary to pneumococcal otitis media of blast origin. The response to chemotherapy was excellent, and the patient was discharged six weeks later with a dry ear, healed drum, good hearing, and no abnormal signs in the central nervous system. No other intracranial complications have been recorded.

Treatment.—Most cases respond well to the "dry" method of treatment—i.e., dry toilet of the canal down to the drum until all pus and debris have been removed, and the installation of dry gauze wicks, this cycle being repeated as often as the wick becomes damp. With the local treatment is combined rest in bed for the first week. The appropriate sulphonamide is used if the otorrhoea persists over 14 days, and in these cases a full course of 30 g. is given. Penicillin has not been used in this series. Nasopharyngeal foci are dealt with surgically at an early date, and a cortical mastoidectomy is performed after the lapse of five weeks if the otorrhoea persists.

Prognosis.—This is good when the case is treated in hospital. The average duration of the otorrhoea in the series of 75 cases, from the time of onset, was 18 days, but the mean figure under full hospital treatment and personal supervision, after admission, was 13 days. Of these 75 cases 5 developed acute otitis media after admission, and these were followed through until quite dry; the mean figure for this group was 12 days. Relapses may occur if an acute nasopharyngeal infection arises, or if the perforation remains unhealed and infection is reintroduced via the meatus. An impression gained from out-patient experience is that many cases result from inadequate primary treatment, and in these the outlook with respect to cessation of the discharge is doubtful. Many of these cases of chronic otitis media do well in hospital but relapse a short while after they have been discharged from the wards.

Treatment

Prophylaxis.—The wearing of plugs in the external meatuses might help to lower the incidence of rupture, but it is difficult to find a suitable material which will be firm enough and yet will allow a reasonable standard of hearing. Such a measure is therefore impracticable in modern warfare. A regular six-monthly check of those exposed to the effects of blast offers the best hope of reducing the incidence of severe nerve deafness. Any showing deafness could be removed from the source of trauma before high-grade disability was established. Those possessing healed ruptured drums should be protected from further blast damage in a similar manner.

Uninfected Blast Ruptures.—Since the use of anesthetic aural drops increases the likelihood of infection the ear should be left strictly alone. These patients are warned that it is dangerous to allow water to enter their ears, and swimming is prohibited. Should a coryza develop, forcible blowing of the nose, with the nostrils occluded, is contraindicated. Inhalations of mentholated steam are advised. The prophylactic use of chemotherapy to reduce the incidence of infection is of doubtful help. If employed a full course should be given.

Infected Blast Ruptures.—Treatment should be along the lines already indicated. The need for admission to hospital and for a thorough local toilet is again stressed.

Nerve Deafness.—Little active treatment is possible. Rest from the field, reassurance, and, if tinnitus is severe, a 14-days course of phenobarbitone are employed. Removal from the source of injury is essential.

Prognosis

It is difficult at an early examination to say which ruptures will heal and which will not. In general, extensive gaps in the tympanic membrane are unlikely to close; moderate-sized lesions, involving a third of the pars tensa, have a fair chance of doing so; while small perforations are likely to heal spontaneously, providing there is no complicating factor such as persistent infection. If the edges of the rupture show vascularization a fortnight after the injury, the repair is taking place normally. If no such red edge is seen at the end of six weeks there is little chance of closure. A perforation which has shown no change in three months will not heal spontaneously. The presence of otitis media delays healing until the infection has been controlled, but thereafter the reparative processes often proceed with surprising rapidity. One wonders whether the onset of an otitis is not, on occasion, helpful, the increased local vascularity stimulating fibroblastic reaction. On the other hand, persistent pus is very likely the forerunner of permanent perforation.

Recovery of hearing proceeds at varying rates. Ruptures which heal, leaving little, if any, visible scar, sometimes recover full acuity of hearing to the human voice, providing there is no permanent associated nerve deafness. Fork tests, and the audiometer, usually reveal gaps in the lower-tone register, however. Uninfected, unhealed lesions also, under the same conditions, often recover almost completely. Some cases show a residual middle-ear or "mixed" deafness at the end of six months, and such deafness is likely to be permanent.

Otitis media lowers the hearing until the tissues have recovered from the inflammatory reaction, and may result in a permanent deterioration of this faculty. Therefore, in blast ruptures considerable improvement of hearing is probable, but prognosis as to full recovery should be guarded. It is the degree of associated cochlear deafness that often determines the final acuity of hearing in "mixed" deafness. In nerve deafness of blast origin a guarded prognosis should be given. Many cases recover completely when judged by the spoken voice, but the upper-frequency forks (2,048 and 4,096 D.V.s per second) and the audiometer usually reveal a permanent depression at those frequencies—in most cases developing rapidly up to a certain point, then slowly or no further; a few continue to have a high-grade inner-ear deafness. Any deafness remaining at the end of six months is likely to be permanent.

Tinnitus is apt to be a persistent and annoying symptom in cases of labyrinth deafness.

The Future

With the termination of hostilities many soldiers will return to civilian life with a legacy of their service in the shape of deafness, with or without an otorrhoea. Such a disability is pensionable. Others as they approach the age of 40 years—the age at which idiopathic nerve deafness starts—will become deaf, and may apply for compensation on the grounds of their war service. Such deafness is unrelated to their service and is not pensionable. Unfortunately, the clinical pictures and the audiometric records of blast nerve deafness and of senile deafness are similar. In the differential diagnosis stress will be laid on the history and on the age of the patient.

The routine audiometric recording of the hearing of Service men under the age of 40, prior to their discharge, is urged. A permanent record of the state of the hearing before the onset of possible senile deafness would be available, and this would be of inestimable value to the otologist in assessing this difficult type of case at a later period.

Summary

An outline of an Army otologist's views on the incidence, aetiology, and types of blast injuries to the ears is given.

The high percentage of associated cochlear trauma in blast ruptures is stressed.

Infection after rupture occurs in approximately half the cases, and usually begins within four days of injury.

A half-yearly otological examination of soldiers, to determine the presence or absence of blast deafness, is indicated.

Prognosis is doubtful, and should be guarded. Residual deafness may remain.

Routine audiometry upon demobilization is advocated.

Acknowledgment is made to Brig. H. S. Kendrick, NZM.C., D.M.S., 2 NZ.E.F., for permission to undertake this investigation; and to Sgt. B. E. Conway and Cpl. O. R. Riley, of the NZM.C., for invaluable assistance in record-keeping.

THE HIPPURIC ACID TEST IN PREGNANCY

BY

W. LAQUEUR, M.D. Basle

Pathologist

AND

HIKMET OVACIK, M.D. Istanbul

Resident Assistant

Second Clinic of Obstetrics and Gynaecology, Medical Faculty,
University of Istanbul

Since the hippuric acid test was introduced by Quick (1935) for clinical purposes many investigations have been published stressing its value in the diagnosis of liver impairment. The importance of the test lies, according to Rennie (1942), Higgins *et al.* (1944), and others, in the detection of a general liver dysfunction: rather than as an aid in the differential diagnosis of liver diseases. Its delicacy as a measure of liver efficiency made its use attractive for our purpose, as it might show more conclusively whether or not there exists a real deficiency in the liver metabolism due to pregnancy. The hippuric acid test has been applied to pregnant women previously, so far as we know, only by Neuweiler (1939), who investigated the hippuric acid excretion during pregnancy and the puerperium. He found a generally low output in pregnancy, with a very wide range.

This investigation has been made in our antenatal clinic on 50 pregnant women during the last trimester. No particular selection was made, except that women with the slightest signs of oedema, albuminuria, or hypertension were excluded. Twenty women attending the out-patient department with general gynaecological complaints were taken as controls.

Methods

In order to avoid the often-reported nausea and vomiting after oral application of sodium benzoate, and also a wait of four hours, we used the intravenous modification of the Quick test as described by Quick, H. Ottenstein, and Weltchek (1938).

In the literature very little was to be found about the comparison between the oral and intravenous methods. A comparative study by B. Ottenstein (unpublished) of both methods of application in normal and luetic patients convinced us that the intravenous method is slightly more sensitive than the oral one.

The tests were made in the morning between 9 and 12 o'clock. The patients, who had had a light breakfast at home, were injected slowly with a freshly prepared solution of 1.77 g. of sodium benzoate in 20 c.cm. of distilled water. The injection took not less than 4 to 5 minutes. Most of the patients showed no reaction at all, some a little dizziness during the injection. They were advised to urinate before the injection and then rested for exactly one hour, after which the urine was used for the estimation. Amounts of urine of less than 100 c.cm. were immediately acidified with 25% hydrochloric acid to Congo-red reaction (about 1 c.cm.) and vigorously stirred with a glass rod until precipitation of hippuric acid crystals started. These were allowed to stand for at least one hour in the ice-box. The supernatant fluid was then filtered off with a suction pump and the crystals repeatedly washed with a little cold water until the original container was entirely clean. The filter paper was carefully removed from the funnel and the crystals washed into a small beaker with a little hot water. The crystals were then dissolved by heating and immediately titrated with N/5 sodium hydroxide against phenolphthalein. Calculations were done according to the original prescription by Quick (1936), and the results expressed as milligrammes of benzoic acid. If the excreted urine was more than 100 c.cm. it was first slightly solidified with acetic acid and concentrated to about 50 to 70 c.cm. on a boiling-water bath. The estimation was then made as described above.

Results

Control Group (20 women, non-pregnant).—Mean average, 0.768; range, 0.41–1.10; standard deviation, 0.22; standard error, ± 0.05 ; coefficient of variation, 29.1%.

Pregnant Women (50 cases).—Mean average, 0.43; range, 0.15–0.76; standard deviation, 0.16; standard error, ± 0.02 ; coefficient of variation, 37.2%.

Discussion

The findings of Neuweiler (1939) were fully confirmed. In late pregnancy there was a marked decrease in the excretion of hippuric acid after intravenous injection of sodium benzoate. In our series only one of the pregnant women reached the level of the mean average of the control group. On the other hand, four of the 20 controls showed a rather low output and two more showed a value slightly under 0.7. This figure is generally accepted as the lower limit of normal. These patients had no symptoms which could explain the low values. Therefore, as some non-pregnant women show a decrease in hippuric acid excretion and some pregnant women have only a slight diminution of the normal excretion, one has to be cautious in drawing conclusions. One has to consider whether the doubtlessly existing lowering of the hippuric acid excretion might be only the expression of a physiological peculiarity of the state of pregnancy. According to Quick (1931), the benzoic acid is conjugated in the liver with glycine, thus forming hippuric acid, which is excreted by the kidneys. If no food rich in glycine is taken previously the glycine is synthesized in the liver at a constant rate roughly proportional to the surface area of the patient, provided the ingested dose of benzoic acid is big enough. Since the excretion of hippuric acid by the kidneys is even faster than its synthesis (Quick, 1931), a low rate of excretion after administration of benzoic acid in the almost fasting state is a measure of the ability of the liver to synthesize glycine. But as in kidney impairment there is a retardation in the excretion rate of formed hippuric acid (Snapper and Grünbaum (1924) have found an increase in hippuric acid in the blood after administration of benzoic acid in cases of renal sclerosis), this possibility has also to be considered, since retention of nitrogen during pregnancy is quite common. The intake of benzoic acid and glycine in a fairly large amount would clarify this question. Investigations on this line are in progress.

Considering theoretically all possible explanations of our findings in view of the peculiarity of the state of pregnancy, there remains another problem to be discussed. Again according to Quick, together with the conjugation of benzoic acid

with glycine there is also a conjugation with glucuronic acid, which forms glucuronic acid-monobenzoate. The portion of benzoic acid appearing in the urine combined with glucuronic acid is generally insignificant, owing to the fact that when glucuronic acid-monobenzoate is administered it is eliminated as hippuric acid and the glucuronic acid presumably becomes oxidized. With regard to the occurrence of glucuronic acid in pregnancy very little is known; but we do know that of the total amount of oestradiol in pregnancy a high proportion is converted to the inactive oestriol, and this, at least to a certain degree, is combined with glucuronic acid. It might be hypothetically assumed that there is a greater need of glucuronic acid in the body during pregnancy, and this fact may interfere with the usual conjugation of benzoic acid and glycine. This problem, too, will be investigated and reported on later.

Conclusion

The excretion of hippuric acid has been tested after intake of 1.77 g. of sodium benzoate intravenously in 50 women during the last trimester of pregnancy; 20 non-pregnant women acted as controls.

Most of the pregnant women showed a marked decrease in hippuric acid excretion: an explanation of this phenomenon has been discussed.

The generally low output of hippuric acid after intake of sodium benzoate in pregnancy makes this test inapplicable where hepatic diseases are associated with that condition.

We wish to express our gratitude to Prof. Nasid Erez, director of the clinic, for having given all facilities for making this investigation.

SULPHAPYRIDINE ANURIA IN GURKHAS

BY

C. W. HEALEY, M.C., M.D.

Lieut.-Col., R.A.M.C.; Hon. Asst. Physician, N. Staffs R.I.

(From a Military Hospital in India Command)

From November, 1944, to February, 1945, five cases of sulphapyridine anuria in Gurkhas were admitted to this hospital. Two were treated medically and three surgically. All terminated favourably. Perhaps the most interesting one was the following.

Case History

The patient, a Gurkha soldier aged 18, was admitted to another hospital with bronchopneumonia on Jan. 12, 1945, and was treated with sulphapyridine, 1 g. four-hourly, along with vitamin C tablets. Next day he was transferred to a second hospital, where treatment was modified to 1 g. of sulphapyridine every six hours. This treatment was continued during the 14th and 15th, when his general condition showed a marked improvement and chest examination revealed only rhonchi scattered throughout the lungs.

At 6 a.m. on Jan. 16 the patient, whose output of urine was diminishing so that fluids were pressed, complained of severe pain in the epigastrium and painful micturition. The sulphapyridine was stopped immediately, after 23 g. had been given, and the patient received the usual medical treatment for sulphonamide anuria. Later that day he was transferred to this hospital, 25 miles away. He had last passed urine (4 oz.: 114 c.cm.) about midnight on Jan. 15/16.

On arrival at 9 p.m. on Jan. 16 the patient was complaining of frequent vomiting and of severe cramp-like epigastric pains. He thought that during the journey he had passed a few drops of urine with much straining. He was drowsy and slightly cyanotic. T. 97.4° F. (axilla); P. 120, rhythmic, equal, full; R. 36; B.P. 115/85. Pupils were miotic and reacted sluggishly to light; tongue dry and furred; ankle- and knee-jerks brisk; cryaesthesia. Examination of the lungs did not reveal any area of consolidation, but only generalized rhonchi and gross rales.

He was examined and his bladder washed out with luke-warm sodium bicarbonate solution. Medical treatment was continued, with

plenty of fluids and alkalis by mouth and by applications in both kidney regions. With his vomiting the patient received three round worms. At 2 a.m. on the 17th he passed with difficulty a few drops of smoky urine. He was also given a continuous intravenous drip of glucose saline. At 8.30 a.m. after a little sleep he felt more comfortable. His intake of fluid in this hospital so far had been 45 oz (1.1 l.), but no urine other than the few drops already mentioned had been passed. His condition was satisfactory except that he was rather drowsier than before. T 96.2° F, P 70, R 22, hard full, R 36, BP 145/100, blood urea 48 mg per 100 ccm. Condition of the chest unchanged. Medical treatment was continued all day and the bladder was washed out twice without result. At 5 p.m., in view of the persistent anuria and the progressive increase of the uraemic symptoms, operative treatment was decided upon. A resection of 200 ccm was done, followed by an intravenous drip transfusion of glucose saline. At 6.15 p.m. the patient was given an injection of morphine. At 7 p.m.—47 hours after the anuria had begun—right-sided nephrotomy was carried out under local anaesthesia.

At operation the kidney was found enlarged and congested, and showed small localized subcapsular swellings containing urine, an incision from the convex border to the pelvis was made for a length of about 1½ in (4 cm) and a rubber catheter stitched in. Lavage of the pelvis with a solution of sodium bicarbonate was carried out, followed by lavage of the bladder with the same solution. There was no occlusion of the ureter. After the operation the patient was given a subcutaneous saline injection of 400 ccm and alkalis by mouth at regular intervals. He spent a good night. 1 oz (28.4 ccm) of urine was collected through the catheter, and the bedding was found to be soiled with urine the next morning. He looked better and vomiting had stopped. T 100.2° F, P 70, R 22. At about 12 noon his temperature went up and the clinical examination showed consolidation of the right lower lobe of pneumonia type. Fever of the high remittent type continued on Jan. 19 and 20 (see Chart). During this period the patient passed an increasing quantity of urine by the catheter and per urethram. He looked very ill, cyanosed, and dyspnoeic, so symptomatic treatment was given. The blood urea on Jan. 19 was 55 mg per 100 ccm.

At 4 p.m. on Jan. 18 sodium penicillin treatment had been started 15,000 Oxford units every three hours (concentration 5,000 units per ccm), the potency having been checked by the station laboratory. In the morning of the fourth day of treatment (Jan. 21) the patient looked better, although his local condition remained unchanged and he was found to have developed a bed sore. His temperature was down for the first time after the operation but in the evening it went up again. Clinical examination showed besides the pneumonia of the right lower lobe, the presence of scattered patches of bronchopneumonia in the right upper and left lower lobes. At about 4 p.m. the patient developed a crisis of asphyxia with tracheal rales, which was overcome only by continuous inhalation of oxygen, digitaline, and camphor in oil.

At that time (the catheter had been removed the day before) the patient was passing a fair quantity of strongly alkaline urine, his WBC count was 8,100 and his blood urea 32 mg per 100 ccm. In view of impending disaster, the chance was taken of giving him 1 g of sulphadiazine four hourly. He had his first dose at 5 p.m., and the next morning seemed somewhat improved. The course of the temperature is shown in the Chart. Sulphadiazine was con-

tinued in doses of 1 g eight-hourly until Feb. 1 when it was cut down to 0.5 g eight-hourly (WBC, 5,900) and the next day discontinued altogether. As adjuvant therapy he was given 2 ccm of nikethamide twice daily. His blood urea on Jan. 31 was 22 mg per 100 ccm.

The recovery of the patient was quick and satisfactory, and on March 4 he was discharged from hospital.

Comment

Assuming that the normal precautions taken in sulphonamide therapy were observed (as they appear to have been) before the patient's admission to this hospital there seem to be two possibilities: (a) that the sulphapyridine used had become toxic, and (b) that Gurkhas, having never experienced Western medication, are particularly liable to fail to excrete the products of modern chemotherapy. As however the same consignment of sulphapyridine has been used in several hundreds of cases

of British and Italian patients without any untoward result, the former explanation is considered unlikely.

In all cases burning micturition shortly preceding the oliguria was the first symptom. Cystoscopic examination revealed great haemorrhagic suffusion and congestion of the mucosa of the bladder, obviously making an attempt at urethral catheterization difficult and dangerous. No signs of tubular obstruction were seen at any of the operations. The absence of these—which one would expect to be present if the acetyl-sulphapyridine is to reach such a concentration in the urine as to be precipitated in the lower third of the ureter and uretero-vesical orifice—and the free passage of the bicarbonate solution which was introduced into the pelvis of the kidney to the bladder, rule out any possibility of mechanical obstruction of the renal tract as the cause of the anuria in the three cases. At no time has any crystal of a sulphonamide derivative been seen either at operation or in the urine, even in concentrated.

The operation revealed in all three cases a kidney without signs of hydronephrosis of the pelvis but small subcapsular swellings containing urine. The kidney, especially the medulla, was found congested. We believe that this condition of congestion—a toxic nephrosis—of the kidney may be the primary cause of the anuria.

The blood urea which has been found to approximate closely in Gurkhas to the normal European standard, rises rapidly, especially in the second 24 hours after anuria has become established, reaching not far from 60–80 mg per 100 ccm after 24 hours. We consider it advisable to try medical treatment for the first 24 hours after the onset of burning micturition and oliguria and to resort to surgical measures if such treatment meets with no success.

It is regretted that owing to Service conditions no bibliography is available.

I should like to express my thanks to the various members of the hospital staff—Indian and Italian—and especially Cap. Del Rio M. of the Corpo Sanitario Italiano and Major B. L. Parnell, I.M.C. for their excellent work and local co-operation, also to Col. K. S. Master M.C. K.H.P. for his kind interest and permission to publish this note.

ACUTE PANCREATITIS

BY

NORMAN G. GODFREY, F.R.C.S.

Surgical Specialist (Full-time Temporary) Criminal Hospital, Manchester

Acute pancreatitis is one of those conditions concerning which it is difficult to formulate definite ideas as to diagnosis and treatment for the disease varies enormously in its severity and statistics as to the mortality rate under different forms of treatment are often misleading. This article is written in an endeavour to clarify some points concerning its diagnosis and treatment.

Before considering the diagnosis it is necessary to stress several facts which are well known.

(1) The disease varies from an extremely severe case with a condition of a mild abdominal upset, which in the majority of cases is not recognized as a pancreatitis.

(2) A definite clinical diagnosis is extremely difficult. In a study of recent literature on acute pancreatitis the following findings are of significance: Pre-operative diagnosis. All cases were operated upon at varying intervals from the time of onset of symptoms. In those operated on under 72 hours from onset the pre-operative diagnosis was incorrect in a much higher proportion of cases.

Pre-operative diagnosis
Acute cholecystitis
Acute pancreatitis
Perforated peptic ulcer
Acute appendicitis

Cases
25
18

Criteria for a Diagnosis of Acute Pancreatitis—In considering the diagnosis of acute pancreatitis in a series of cases it is necessary to have some criteria on which the diagnosis is based. In this series, and in the cases taken from the literature the diagnosis has been made on one or more of the following: (1) evidence of acute pancreatitis seen at necropsy, (2) evidence of acute pancreatitis seen at operation, (3) clinical evidence associated with a urinary diastase above 50 units. Any cases which clinically may have been acute pancreatitis but did not fulfil one or more of the above conditions, have been excluded from this discussion.

Differential Diagnosis

Figures taken from the literature and from our own cases show that the two most common conditions with which acute pancreatitis is confused in the clinical diagnosis are perforated peptic ulcer and acute cholecystitis. The treatment of perforated peptic ulcer is early operation, whereas in acute cholecystitis (although fashion changes from time to time) most surgeons adopt a conservative attitude, operation being performed as an emergency only when certain pathological changes occur which make it dangerous to continue with conservative treatment.

It is my belief that the most severe cases of acute pancreatitis, particularly in men, simulate perforated peptic ulcer, and the less severe cases simulate acute cholecystitis. In the cases of acute pancreatitis mistaken for perforated peptic ulcer, operation is performed and the mortality is high. In the less severe cases, mistaken for acute cholecystitis, conservative treatment is adopted and the mortality is lower. The result of this is that the mortality for operation is higher than for conservative treatment; but this gives a false picture of the effect of operation on the mortality, because the cases diagnosed pre-operatively as perforated peptic ulcer are the most severe ones and will have a high mortality rate in any case, although the added strain of an operation must increase the rate, but not to the extent which is implied by a comparison between the conservative and operative treatment.

If laparotomy is performed because of doubt or mistaken diagnosis it seems logical that the least possible intra-abdominal interference should take place. Decompression of the biliary system by means of cholecystostomy may be advisable, and drainage of any large collection of fluid in the lesser sac.

Analysis of Cases

Thirteen cases of acute pancreatitis in which the diagnosis was confirmed by one or more of the criteria mentioned above were treated at Crumpsall Hospital during the four-year period 1941-4. Ten of these cases were submitted to operation; the pre-operative diagnoses of these cases are as follows:

Cases Submitted to Operation within 60 Hours of the Onset of Acute Symptoms

Pre-operative diagnosis:	Cases
Perforated peptic ulcer	2
Peritonitis	2
Acute cholecystitis	1
Acute intestinal obstruction	1

Cases Submitted to Operation 10 to 30 Days after the Onset of Symptoms

Pre-operative diagnosis:	Cases
Cholecystitis	3
Pancreatitis	1

As an explanation of the diagnosis of the cases submitted to early operation it should be noted that acute pancreatitis was considered in at least four instances, but because of uncertainty it was thought unwise to continue with conservative treatment.

Suggested Procedure

In a case where the diagnosis of acute pancreatitis is a possibility one must first consider whether it may be a perforated peptic ulcer, and if reasonable doubt exists laparotomy must be performed. If at operation an acute pancreatitis is found the most that should be done is decompression of the biliary system by means of cholecystostomy, and drainage of any large collection of fluid in the lesser sac. Acute pancreatitis is associated with gall-stones in a high proportion of cases, and if there is an impacted stone at the neck of the gall-bladder cholecystostomy is useless unless the stone can be removed. In such a case cholecystectomy should be performed if the general condition of the patient allows it. Gastro-intestinal suction should be used in all cases, whether treated conservatively or by operation.

If the diagnosis of perforated peptic ulcer or any other condition requiring urgent intervention can be eliminated, conservative treatment should be adopted. Conservative treatment means careful periodic examination of the patient, with an hourly record of the pulse rate, continuous gastro-intestinal

suction, administration of intravenous therapy (preferably plasma), and an estimation as soon as possible of the blood or urinary diastase. Whipple (1942) prefers the serum lipase test of Myers, which, he states, can be performed within an hour by those experienced in its use. At a later date a radiological examination of the gall-bladder should be performed, and if stone or non-function of the gall-bladder is demonstrated, operation must be undertaken.

Summary

In acute pancreatitis a diagnosis of perforated peptic ulcer or some other surgical emergency will be made in approximately 40% of the cases and laparotomy be performed. The mortality rate will be high in these cases, chiefly because they are the most severe.

Where the diagnosis of acute pancreatitis or acute cholecystitis is made the patient should be treated conservatively on the lines described. In these cases the mortality rate will be lower, chiefly because they are less severe.

In the mild cases the diagnosis of acute pancreatitis will often not be made.

Medical Memoranda

A Fatality from Thyroidectomy following a Leucopenia caused by Thiouracil

There has recently been considerable interest in the treatment of thyrotoxicosis by the administration of thiouracil. It is difficult to assess the value of any new drug without extensive trials; the publication of a single case report is probably of little value of itself, but when taken in conjunction with others it may help to form a basis of opinion.

CASE HISTORY

Mrs. A., aged 67, was admitted to the Royal Victoria and West Hants Hospital, under Dr. Robson, as a case of heart failure. For the previous 15 months she had suffered from increasing dyspnoea, especially on exertion, and swelling of the ankles. She experienced no cardiac pain or palpitations. She had a slight productive cough but had never had any haemoptysis. Appetite was good, and there was no loss of weight. Her symptoms had increased markedly during the month before admission, so that any slight exertion tired her. Her previous history contained nothing relevant. There was no record of rheumatic fever or tonsillitis.

On admission the patient was fairly well covered and there was no apparent recent loss of weight. She had a well-marked exophthalmos, with a moist skin and slight tremor. She did not appear to be very nervous. She had a pronounced auricular flutter with a pulse rate of 120. The apex beat was 4 in. (10.2 cm.) from the midline, in the fifth left intercostal space. A systolic murmur was heard over the cardiac area, with maximum intensity over the apex beat; a mid-diastolic murmur was also present. There was evidence of back pressure, with oedema and pitting over the lower limbs and back. Some crepitations were heard at the bases. The liver was not enlarged. There was a uniform enlargement of the thyroid, which was smooth and fairly firm. A systolic murmur could be heard all over the gland.

Radiological examination of the chest showed gross cardiac enlargement with back pressure. The urine contained no casts, but there was a slight trace of albumin. The blood urea was 37 mg. per 100 c.cm. Blood count: erythrocytes, 6,160,000 per c.mm.; Hb, 62%; colour index, 0.5; leucocytes, 7,000 per c.mm. (polymorphs 68%, lymphocytes 24%, monocytes 8%).

She was treated with digitalis and sedatives at first, which improved the rate and regularity of her heart. She was then put on a course of Lugol's iodine, which was discontinued on account of persistent diarrhoea. A course of mercurial diuretics was then tried, with some improvement. It was decided to start her on a course of thiouracil, owing to her apparent intolerance of iodine. She received daily injections of 0.3 g. for one week, at the end of which time she was found to be suffering from a leucopenia, her leucocytes having dropped to 3,900 per c.mm. (polymorphs 60%, with a relative lymphocytosis). An immediate injection of 10 c.cm. of peritoneal nucleotide restored her leucocytes to 8,200, with 80% of polymorphs. However, four days later her leucocytes had fallen to their original level. Her general condition had improved with thiouracil; whereas she had lost a stone (6.3 kg.) in weight during one month's treatment in hospital, she now started to gain. As her blood picture remained unsatisfactory she was given daily injections of 10 c.cm. of peritoneal nucleotide, which produced only a temporary improvement in her leucocyte count. These injections, however, brought about a severe general reaction, with a rise of temperature and pulse rate. After three weeks' treatment, with no permanent improvement in her blood picture, her thyrotoxicosis began to become more apparent, with a

return of her fibrillation. It was decided that her only chance of recovery lay in a thyroidectomy. She died before the operation course of Lugol's iodine. Her leucocyte count a day before operation was 4400 per c mm.

Operation was performed under avertin gas-oxygen and local anaesthesia. Seven-eighths resection of the gland was carried out. Her condition on return from the theatre was fairly satisfactory with a pulse rate of 90. She was unable to retain any Lugol's iodine given by the rectum and intratracheal feeding was not needed. Some eight hours after operation her pulse rate rose sharply to 140 and she became very restless. She apparently died of a circulatory crisis some 24 hours after operation.

COMMENT

This case presented the familiar problem of an elderly thyrotoxic patient with advanced cardiac damage. The difficulty arose from her intolerance of iodine. Thiouracil produced an improvement in her toxic condition but the effect was offset by the apparent irreversible change in her blood picture. Pentnucleotide produced only a temporary improvement which was accompanied by disturbing general reactions. This might have been overcome by the administration of extract of yellow bone marrow given by the mouth. This case is the first fatality in a small personal series of under 100 thyroidectomies which included some severe thyrotoxic cases with concomitant heart damage.

My object in reporting this case is to stress the danger of subjecting a patient to thyroidectomy with an uncompensated granulocytopenia, even if the other indications for operation appear to be urgent.

Assistant Surgeon, Royal Victoria and West Hants Hospital, Bournemouth

Palindromic Rheumatism

This syndrome seems so clear-cut that it is strange in view of the widespread interest shown in rheumatic conditions over the last 20 years, for it to have escaped notice in the U.S.A. until four or five years ago and, here, until Winfield (1945) reported a case in the *Journal*. Hench and Rosenberg (1941, 1944) the former a leading authority on rheumatism, described 34 cases from the Mayo Clinic and Cain (1944) one case. No excuse at any rate, need be made for reporting further cases as they come to notice. The symptoms and signs presented by a patient seen in Sept., 1945, accord closely with the accounts given already.

A housewife aged 53 was sent to Droitwich for treatment for arthritis. She gave a history of four years of frequent brief acute attacks of pain, swelling, and redness of her joints, or of the tissues near them, lasting a few hours to six days, generally three days. The intervals were quite irregular. Some malaise occurred during the attack, but the temperature was never raised. She was perfectly well, with no joint symptoms whatever between the attacks. These often started at night. The hands, knees, or feet were usually affected.

The patient was a healthy well nourished woman with a slightly enlarged thyroid but no symptoms or history of hyperthyroidism. She had never had a doctor except for her six confinements and for the present condition. There was a small patch of inflammation on the dorsum of the left foot, which cleared up within 24 hours and a small subcutaneous nodule near her right elbow. During her stay of three weeks her right wrist the subcutaneous tissue at the nape of the neck, and her left ankle were affected in turn for three to four days. Her temperature was at all times normal. The B.S.R. was normal in two of the intervals but was raised (28 Westergren) during the last episode. The blood count, blood uric acid urine, and x-ray appearances (hands and knees) were normal. Salicylates had no effect.

Following biopsy, Hench and Rosenberg describe (a) typical inflammatory joint reaction, (b) inter- and intra-cellular oedema of the skin, (c) low-grade non-specific reaction in the nodules. As to aetiology, they reject infective allergic and angioneurotic possibilities, there is then for the moment, even less of a clue to it than in rheumatoid disease the condition which the syndrome most closely resembles. It would appear, however, that anxiety and strain may play, at any rate a predisposing part in both conditions. Thus the one patient in the Mayo Clinic group who lost her attacks completely did so after she "quit worrying and adopted a baby," and another had less severe attacks after he "quit the oil business became a druggist, and took phenobarbitone daily," while the patient whose case is described here started hers after months of great war strain and of anxiety about her son, who had disappeared in Malaya.

Reviews

A YEAR'S BIOCHEMISTRY

Ann. Rev. Biochem. Vol. XIV, Ed. by J. M. V. L. L. Alabaster Ed. J. M. V. L. L. (Pp. 633) Clarendon Press, Oxford University Press, London H K Lewis & Co

Without any externally visible enlargement this book exceeds its predecessor by yet another 60 pages, a 10% or future indefinite expansion involving the supply of a mechanical crane along with each new edition float before a semi-stunned reviewer's mind's eye. Perhaps however time are not quite so desperate the rate of increase may be accelerating for last year (see review in the *Journal* of Nov. 18 1944) we had to register an increase of 90 pages.

Once more the editors have drawn their contributions from the British Commonwealth as well as predominantly from the United States. Two of its year's experts are from Britain and three from Australia, the remainder are American authors. Again although most of the contributors derive from academic laboratories—universities, medical schools and research institutions—inspection of the various authors' places of work, reveals that three out of the forty were engaged in industry—a rather smaller proportion than in Vol. XIII.

An admirable balance is once more maintained between, on the one hand the chemical and the biological aspects of fundamental biochemistry and on the other, between the old and their application. Thus we have again chapters on biological oxidations and reductions and on non-oxidative enzymes, on the chemistry of the carbohydrates of the lipids and of the amino acids and proteins, on the water-soluble and on the fat-soluble vitamins, on carbohydrate metabolism, on fat metabolism, on protein and amino acid metabolism, on mineral metabolism, on the chemistry of the hormones, on the chemistry and metabolism of phosphorus compounds, on the steroids and the nucleic acids. These hardly welcome perennial are enlivened by the usual addition of bright new annuals. This year's chapters are devoted to the interpenetration, to animal proteins (chlorophyll pigments were surveyed last year) to detoxication mechanisms to biological nitrogen fixation, and (a complementary story) to the nitrogenous constituents of plants and also to their mineral nutrition. At the very end are two chapters on subjects of topical and still growing interest—namely, the chemistry and metabolism of bacteria, and the chemistry of antibiotic substances other than penicillin. The author of this last chapter, Dr A. E. Oxford writes "By reason of a regulation designed to ensure the better prosecution of the war effort, the first article in the *Annual Review of Biochemistry* to deal exclusively with a comparatively new but rapidly growing field in microbiological chemistry cannot include anything about the most remarkable substance in that field—namely, penicillin. This is the less to be regretted since penicillin ought undoubtedly to have a review to itself when publication upon its purification and chemical nature is again permitted." Already his prophecy has been in part fulfilled with the publication of the surviving two alternative formulae out of the many that have been so assiduously and secretly elaborated, studied and rejected during the past four years. It can be confidently anticipated that next year's Review will contain something like the account forecast by Dr Oxford.

Meanwhile there is still only one word that is indispensable to the description of this annual source of satisfaction and humility: the word is—indispensable.

PSYCHOLOGICAL MEDICINE

Psychological Medicine: A Short Introduction to Psychiatry. With an Appendix on Psychiatry Associated with War Conditions. By Desmond Curran, M.B., F.R.C.P., D.P.M., and Eric Guttmann, M.D., M.R.C.P. Foreword by J. J. Connelley, D.M., F.R.C.P. Second edition. (Pp. 216) Illustrated. 10s 6d plus 6d postage. Edinburgh: E and S Livingstone.

Among the very numerous books which have been written on this subject in recent years this volume may be described as outstanding, and the publication of a second edition in two and a half years and at a time when the issue of books is so difficult shows that the medical public has appreciated this fact. Its great merit is its brevity, its clarity, and its middle course.

between the extremes of any of the many psychiatric doctrines which have flourished in our time.

Written perhaps more from the point of view of the psychoses than the psychoneuroses, it yet manages to hold a just balance between the two branches of mental medicine, and the addition of a new chapter on the obsessions adds materially to its value. The sections on the organic syndromes, especially that on the results of head injury, are especially valuable; and the appendix on psychiatric conditions of war, brought up to date, is of great interest. The importance of personnel selection in relation to general morale and prevention of mental illness is admirably illustrated, especially as exemplified by the absence of neurosis in the carefully selected submarine crews, engaged in a service which, at first sight at least, might have been expected to result in exceptional mental stress.

It remains to be seen whether the lessons of war can be carried into the medicine of peace, and whether the profession as a whole can think a little more of the community and a little less of the individual as an exercise in "scientific curiosity." As Dr. Conybeare says in the foreword which he has provided: "It is clearly better that the diagnosis of the occasional case of physical disease should be delayed rather than that large numbers of potentially useful men should be rendered hypochondriacs." Yet one must try to keep a just balance, and it is equally important that we should not dismiss the patient as "merely neurotic" because his symptom-complex defeats our diagnostic acumen, if we have not got any positive evidence for such a conclusion. If all medical practitioners were to read and ponder over this excellent little book it would help them greatly to avoid the Scylla and Charybdis of these two equally common states.

TUBERCULOSIS IN THE U.S.A.

Tuberculosis in the United States, Graphic Presentation, Vol. 1. Mortality Statistics for Large Cities. Federal Security Agency, U.S. Public Health Service, and Medical Research Committee, National Tuberculosis Association.

This volume is the third of a series dealing with tuberculosis in the United States of America. Vol. 1 reviewed the mortality from tuberculosis over three decades for States and geographical divisions by age, sex, and race. In Vol. 2 the data were presented in the form of proportional mortality. Considerable variation exists between and within States; the death rate for tuberculosis in the triennial period 1939-41 was 411 per million in the rural areas and 554 in the large cities—35% higher. The present volume deals with the mortality experience of the 92 cities with a population of 100,000 or more. The data are set out in two tables and two diagrams, for each city. The first table shows the death rate in eight age groups for each sex and race for the period 1939-41, together with the crude and standardized rates. The second table gives, for the same subdivisions, the deaths from tuberculosis as a percentage of deaths from all causes. The crude death rates for all races and for whites range from 156 per million in Grand Rapids to 1,517 in San Antonio; age and sex differences do not contribute to this large range, since the standardized death rates are 155 and 1,569 respectively. The non-white death rate varies from 955 per million in Charlotte to 2,755 in Newark.

In each of the three volumes the graphs are on the backs of the tables, a more convenient arrangement from the reader's point of view would have been for the tables to face the graphs.

A DOCTOR'S LIFE AT SEA

Ship's Doctor. By Rufus W. Hooker, M.D. (Pp. 175. 15s.) London: Herbert Jenkins, Ltd.

This medical book, the autobiography of an American sea surgeon, could equally well be read by the lay public. The greater part of the volume is concerned with recounting cases that came under the author's care during his voyages in passenger liners and pleasure cruisers.

Dr. Hooker began his medical career in Mexico, and would have remained there but for the overthrow of the Diaz regime in 1911, when the revolution declared an "open season" on aliens. He had to throw up his work and escaped with only his instruments. He then went through a course of postgraduate study in New York hospitals and specialized in diseases of the eye and ear. During the 1914-18 war he was posted to an

aviation training camp; later he worked up a successful general practice in his home town, but his longing for world travel turned his thoughts to sea-going and he became ship surgeon, a job for which he was well qualified. He possessed medical and surgical experience and was self-reliant—the two chief requisites for medical life at sea. Perhaps in no other branch of our profession has a doctor to face such a wide range of cases, frequently urgent, beyond reach of other help.

Into a connected story he weaves clinical accounts of how he dealt with myeloid leukaemia, tropical diseases, fractures, abdominal emergencies, and many other complaints. His medico-legal cases are full of interest, as also his management of accouchements at sea. Prospective ship surgeons should give their attention to this book, which tells in easy fashion the kind of professional life that has to be faced in surroundings that are usually devoid of the help so readily obtainable in practice ashore. It is a book of medical and surgical realism rendered all the more attractive by the author's common-sense reflections and independence of thought.

Notes on Books

The 53rd edition of the *Annual Charities Register and Digest*, for 1946, is published by Longmans, Green and Co. on behalf of the Charity Organization Society, which has now been renamed the Family Welfare Association. As in former years, this reference book gives information about the societies, associations, and other bodies that provide relief in affliction and distress of all kinds. The title-page describes it as a classified register of charities in or available for the Metropolis, but in fact it gives pointers to many other agencies and organizations. The information is grouped into forty-three sections and there is a full index. The head office of the Family Welfare Association is at Denison House, 296, Vauxhall Bridge Road, London, S.W.1, from which address copies of the book may be had direct, price 10s. 6d.

Mr. ZACHARY CORN's *Early Diagnosis of the Acute Abdomen* appeared first in 1921, and by 1944 had passed through eight editions and seven reprintings. As a guide to the diagnosis of abdominal emergencies this little book met a real need, and the profession was quick to recognize its value. The ninth edition (Oxford University Press; 12s. 6d.) carries on the good work, and the author in preparing it has made a few minor changes and additions, chiefly in the chapter on acute intestinal obstruction and on acute abdominal symptoms in pregnancy and the puerperium, and has included two more diagrams. A further lease of popularity can be predicted.

Volume LXIV of the *Transactions of the Ophthalmological Society of the United Kingdom* covers the proceedings of the Society during its 64th session—March and April, 1944—and includes reports on the affiliated societies for 1943-4. It is published by J. and A. Churchill at 40s. The main subjects dealt with are ocular psychoneuroses, virus diseases of the eye, diseases of the brain and optic nerve, diseases of the orbit and sphenoidal sinus. The volume opens with Mr. H. M. Traquair's presidential address on the nerve-fibre bundle defect, and the miscellaneous papers include one by Richard Cruise on preventable blindness in war.

Fabian Publications Ltd., and Victor Gollancz Ltd., have jointly issued a shilling pamphlet, *The British Gas Industry—Present and Future*, by JOAN MURPHY, as No. 103 of the Fabian Society's research series. Leslie Hardern in his foreword says that the time has come: "the new Government is completing its plans for the nationalization of the coal industry, and will soon be turning its attention to the gas and electricity industries." In three sections the author gives facts about the gas industry to-day, discusses present problems, and outlines a plan.

A second edition (1945) of the *Dietitians Section of the National Register of Medical Auxiliary Services* has been issued, and copies of this and other sections will be sent free to medical practitioners, hospitals, etc., on application to the Registrar of the Board, 111, Tavistock Square, London, W.C.1. The list comprises the names, addresses, and qualifications of persons approved by the recognized qualifying body, the British Dietetic Association. Dietitians is defined as the interpretation and application of the principles of nutrition in health and disease. Dietitians whose names appear in the list do not in cases of disease undertake the treatment of any condition except under the direction and control of a registered medical practitioner.

TREATMENT OF PEPTIC ULCER

Treatment of a common disease like peptic ulcer is so often determined by impressions or by the prevailing climate of opinion that it is important from time to time to check our practice with the statistics of a carefully observed series of cases. An account has now been published¹ of over a thousand cases which have been carefully followed at the surgical department of the New York Hospital. As the majority of the patients were treated medically, this is probably as dispassionate a record as can be expected of the results of medical and surgical treatment of peptic ulceration; but inevitably it deals with a highly selected sample of the disease. At one time or another 10% of people suffer from peptic ulcer, but only a fraction of them reach the out-patient departments of the hospitals, and of those who do only about 1 in 6 filters through into the wards. Hospital statistics such as Dr Heuer's are therefore applicable only to the small group of ulcers which have perforated, bled, or resisted ambulant treatment. Moreover, though the book is described as a ten-year clinical study, less than a quarter of the patients had been followed for more than five years, and only 120 of them had gone so long without operation. Dr Heuer's experience, both in the groups of patients treated conservatively and in those submitted to operation, has been that the results change considerably until at least five years have elapsed, and even in the period between five and ten years a certain proportion suffer a recurrence. This is indeed a field in which experience is difficult and judgment fallible. Much of the disagreement about the relative merits of medical and surgical treatment of peptic ulceration has arisen from the failure of physicians and surgeons to realize that they are often dealing with different categories of experience, and that in the life-history of a peptic ulcer a decade is a relatively short time.

In this group of patients with peptic ulcers admitted to hospital Heuer finds that less than 60% have done well on medical treatment and 3.5% of those so treated have died directly from the ulcer. Serious complications which lead to death usually appear early in the period of observation, and it is unwise to persist with medical treatment if pain is not relieved or if complications occur. Haemorrhage, gastric retention, and gastro-jejunal ulceration should all exert a strong bias in favour of surgical treatment. Heuer believes that the immediate treatment of haemorrhage should be medical, but if haemorrhage recurs, or if a patient bleeds while he is in hospital undergoing medical treatment, it is probable that the bleeding is arterial and surgery should be advised. In view of the possibility of operation, particularly in patients over 45, Heuer is opposed to the Meulengracht treatment by early feeding, and claims equally good results from parenteral fluids. There can be

few questions on which physicians and surgeons differ so widely as the risk of carcinoma in gastric ulcer. Heuer believes that with careful examination and supervision the risk of missing a carcinoma by medical treatment of gastric ulcers is not great—certainly not greater than the risks of gastric resection. In his experience a low acidity, must give rise to the strongest suspicion of carcinoma.

From analysis of the results of surgery Heuer comes to two conclusions with which many physicians will agree. Gastro-enterostomy is often a most successful operation and it is still the operation of choice in a high proportion of cases of peptic ulcer; and, secondly, the success of the operation varies very much with the skill of the individual surgeon, and particularly with his ability to know how and where to put the stoma. When, however, gastro-enterostomy or other conservative operation fails, nothing short of gastric resection will succeed and any lesser interference is usually disastrous. After gastro-enterostomy there is no significant change in the secretion of hydrochloric acid, and it is assumed that the good results are due to dilution and neutralization of the acid. After gastric resection there is, in general, a decline in acid secretion in proportion to the extent of the resection, but resection of any magnitude consistent with a reasonable mortality does not ensure achlorhydria. If we are ever to achieve complete achlorhydria as the basis of cure of peptic ulcer it will probably come not via surgery but via biochemistry, on the lines promised by Davenport's² work on the inhibition of gastric secretion. While agreeing with Heuer's conclusions and stressing the clarity and objectivity of his writing we cannot help adding that his monograph would have been still more acceptable if he had taken some statistical advice in the presentation of the data. To say that "the results of gastro-enterostomy approach within 10% those of resection and with a lower primary mortality" is almost meaningless and a better picture of the relative merits and mortality of gastro-enterostomy and gastrectomy could almost certainly have been composed from these figures if the chances of dying or recovering after different operations had been compared by quite simple statistical techniques. The same criticism applies to Dr. Heuer's analysis of the literature, where the data are so discordant that they cannot properly be summated and expressed as percentages. Much of the literature is in any event of little value owing to the high proportion of cases lost sight of. It is nevertheless clear that treatment of peptic ulcer consists to-day of a series of screens, whereby the more tractable cases are successively filtered off—rest in bed for those in whom ambulant treatment fails, gastro-enterostomy when medical treatment fails, and gastrectomy for the unsuccessful gastro-enterostomy or for the patient who bleeds or is suspected of malignant disease. In recommending any treatment for wide application we must always be mindful of the enormous reservoir of cases of peptic ulceration and of the contribution which the biochemist may make to treatment within the next five or ten years. Nevertheless there will be few physicians or surgeons, who will not have their ideas in clearer focus as a result of reading this analysis of American experience of the disease.

FUTURE OF MENTAL NURSING

The report of the Subcommittee on Mental Nursing and the Nursing of the Mentally Defective,¹ summarized in our issue of Jan. 12, is to be welcomed on every count. The subcommittee saw as its main task the formulation of recommendations which would have the effect of raising the standard and status of mental nursing to the same level as general nursing. Such a plan would be vain if it were not justified by the facts, and if the same level of skill, intelligence, and devotion were not required in the nursing of the mentally ill as of the bodily ill. Until a few years ago this could, perhaps, hardly have been claimed. By far the greater part of the nurse's time was then spent in a largely custodial care of her patients, which, though it made demands on such qualities as experience, tact, and presence of mind, did not need such a high level of technical education as was necessary in general nursing. In these last few years, however, the face of psychiatry has changed. The appearance of a range of physical methods of treatment has brought with it a need for the nurse to have knowledge and experience of specialized techniques, an understanding of the modes of interaction of bodily and mental events, and therefore a greater knowledge both of general medicine and of psychology; it has above all meant a reorientation of her attitude to her patient. It is no longer a matter of passively waiting for him to get better, and tiding him over the difficulties and dangers that lie in his way, but one of actively aiding his recovery. Every patient that comes into the admission villa offers a challenge; it should be possible to get him well and on his way home before the question of transfer to a chronic ward arises. The mental hospital, from an asylum, is in process of becoming a hospital much like any other.

One of the principal recommendations of the subcommittee is that the system of examinations should be unified. One certificate is issued by the Royal Medico-Psychological Association, another by the General Nursing Council. Though it is only the latter which entitles the nurse to State registration, the R.M.P.A. certificate attracts about nine entries for every one for the State final. The reasons are not far to seek. The R.M.P.A. certificate offers nearly all the advantages in pay and promotion of State registration, and the examinations are conducted at a much larger number of centres, at a lower fee to the nurse, and are easier to pass. The preliminary examination for the G.N.C. certificate particularly receives criticism from the subcommittee for being but poorly adjusted to the nurse's experience in the mental hospital at that stage. From the report of the subcommittee it is clear that in the past there have been negotiations between the Royal Medico-Psychological Association and the General Nursing Council, with a view to ending this state of affairs, which have broken down through no lack of readiness to compromise on the part

of the R.M.P.A. While recognizing the great services of the R.M.P.A. to mental nursing ever since it held its first examination in 1891, the subcommittee believes that the time has come for its examinations to be discontinued and for the State certificate to be the only one available. Present holders of the R.M.P.A. certificate would have their names entered on the register without further examination, and the representation of mental nurses on the G.N.C. would be strengthened.

A number of excellent reforms are also proposed relating to scales of salary, hours of duty, interchangeability of pension rights, discipline, feeding, amenities, and the private liberties of the nurse. In these connexions the need for securing an adequate entry to the profession has clearly had great weight with the subcommittee. It is recommended that the mental nurse should continue to enjoy in the future as in the past a slightly higher scale of pay than the general nurse. This is justified by the often unpleasant nature of the work, the less favourable prospects of advancement of the mental nurse, and the isolation in which she must often live. It can hardly be doubted, however, that the effect on public opinion will be that a service which has to offer a special scale of remuneration must suffer from corresponding disadvantages; and an improvement in the status of the mental nurse is not likely to be encouraged in this way. We must hope for the time when the reasons for this discrimination are abolished, when prospects of advancement are as good in mental as in general nursing, when there are psychiatric clinics in all our larger towns and not only in often barrack-like buildings in the heart of the country, and when salary as well as status will be the same for both branches of nursing.

The future of the mental nurse will continue to depend on factors which have their effects on a national scale and which did not come within the terms of reference of the subcommittee. One of the most obvious of these is the balance of opportunities offered by other callings for young women and men. This may be regulated by the laws of supply and demand, or planned under a national wages policy. Another factor of primary importance, referred to at some length in the report, is the education policy of the country and the effect it will have in narrowing the gap between the school-leaving age and the age of entry to hospital. Even under present plans this gap will be one of two years, and it is a wasteful procedure by which adolescents are left to find their feet in the commercial market for so long before they have an opportunity of entering the nursing profession. Some possibilities of bridging this gap are discussed in the report, and the conclusion is regretfully reached that none of them are practicable. Would it not be possible to regard the nurse as a public servant as important as the teacher, and to give her the same facilities for a higher education? This could be of a preliminary type equally suitable for the subsequent training of the nurse, the occupational therapist, and perhaps other health workers too.

¹ H.M. Stationery Office. (1s.; post free 1s. 2d.)

EPIDEMIC OF VIRUS B INFLUENZA

During the past few weeks the weekly recorded deaths from influenza in the great towns of England and Wales have reached the highest levels for the past two years. At the same time many practitioners have doubtless been busy in attendance on illnesses of an influenzal character in their practices and perhaps in their own families. We understand that few actual outbreaks in semi-isolated communities have yet been investigated from the laboratory standpoint, though many sporadic cases of respiratory-tract infection, some typical of influenza, have been investigated during the past month. Serological tests on specimens received from various parts of the country have yielded in a considerable proportion of instances results diagnostic of virus B influenza.

It would appear, therefore, that an outbreak of virus B influenza is now in progress in this country. Hitherto virus B has not been incriminated in any widespread epidemic in Britain, though sporadic cases were detected in 1939¹ and a minor outbreak in 1943.² Nevertheless, its potential power of epidemic spread has been shown by experience in the U.S.A. in the recorded outbreaks of 1936 and 1940.³ Both virus A and virus B cause sharp attacks of fever with general symptoms preponderating over those arising from the respiratory tract. Both are apt to be followed by pneumonia, associated with bacterial invasion of the lung, though perhaps the risk of chest complications has in the past been greater with virus A than with virus B infection. Some workers^{4,5} have thought that virus B influenza was of more insidious onset and associated with a greater intensity of coryza and other nasal symptoms than influenza A. These findings were not confirmed by experience in this country in 1943, when the cases of virus B infection appeared clinically indistinguishable from those of virus A in former years.⁶ The present outbreak may afford an opportunity for further observation on these and other points by those who are able to study sharp outbreaks in any community in which patients are admitted to hospital.*

To those who may wonder whether the present prevalence of influenza is indicative of a post-war pandemic such as that experienced in 1918 the present statistics of the influenza deaths in relation to age may be of interest. It is understood that, as yet, no suggestion of an excessive mortality in the 20-40 age groups has appeared, as in the case of the 1918 epidemic. It is chiefly the older age groups of 50 and over in whom the majority of the recent fatal cases have occurred.

A word of warning may not be out of place. In January, 1943, the virus B "wave" was succeeded by a lull, then by sporadic cases and localized outbreaks of influenza A in the spring and summer, and finally an explosive epidemic of virus A developed in the early winter of that year.⁷ It was as though virus B, which possesses no immunological characters in common with virus A, had disturbed the host-virus equilibrium involving the latter organism, and paved the way for the appearance of a widespread epidemic. These occurrences in 1943 may have been exceptional, but they are worth bearing in mind at the present time.

* Those interested should communicate with S.M.O., Med. III, 35 G. Ministry of Health (Whitehall 4300), if circumstances appear to warrant further investigation.

BASAL BODY TEMPERATURE AND THE MENSTRUAL CYCLE

It is now over forty years since Van der Velde described changes in the basal temperature of the body during the menstrual cycle. Since his original description in 1904 knowledge of the physiology and pathology of the endometrium has grown, and it is now possible to correlate fluctuations of body temperature with changes in the uterus and ovaries. Pendleton Tomkins, of Philadelphia,¹ in a paper illustrated with numerous valuable graphs, shows that the curve of body temperature in the normal menstrual cycle is biphasic. Before ovulation the temperature is relatively low. Ovulation is signalled by a fall of temperature followed by a sharp rise to a higher level. Another sharp fall one to three days before menstruation brings the temperature down again to the relatively low level which persists until the next ovulation. If conception occurs the premenstrual fall is absent and the temperature remains at the higher level. In an earlier paper Tomkins² recommended that the temperature be taken by the rectum on waking in the morning, before rising, and before taking food and drink or smoking. The reading must be recorded at once on the special graph. Any indisposition, such as a cold or indigestion, should be noted—even a "hangover" may vitiate the record. Coitus and *Mittelschmerz* should also be noted. Records are not necessary during menstruation. The graph is not considered of value until it has been kept for at least two months; ovulation is indicated by a rise in basal body temperature of 0.4 to 0.6° F.

Commenting on this study, Kleitman³ suggests certain modifications. He finds oral temperatures as efficient as rectal provided precautions are taken, such as resting and avoiding hot drinks within an hour or cold drinks within half an hour of recording the temperature. Kleitman also states that an evening is as reliable as a morning temperature. Kleitman⁴ has shown that the intra-uterine temperature is the most reliable, but he considers that for practical purposes the reading of the basal body temperature is sufficient.

Other workers have correlated temperature changes during the menstrual cycle with changes in the ovaries and endometrium. Greulich, Morris, and Black⁵ examined the ovaries in women submitted to laparotomy and found that the fall of temperature about the middle of the cycle is not necessarily evidence of ovulation; the rise which follows does denote ovulation in most cases. The age of the corpora lutea did not always correspond with the temperature readings, perhaps because temperatures were taken only every twenty-four hours or because the rate of development of the corpus luteum varies. Martin⁶ has checked temperature graphs by endometrial biopsy. He recorded 164 biphasic cycles; in 47 of these biopsy in the second phase showed secretory endometrium. In 17 monophasic cycles, where the rise of temperature in the second half did not take place, there was proliferative endometrium but no evidence of secretory change. Similar findings have been recorded by Halbrecht.⁷ Martin also demonstrated that the difference in basal body temperature between the two halves of the biphasic cycle was statistically significant, but there was no statistically significant difference in the two halves of the monophasic cycle. The temperature curve is therefore a reliable means of distinguishing ovulatory from non-ovulatory menstruation.

This method of determining the time of ovulation needs no expensive apparatus or time-consuming laboratory work. Barton and Wiesner⁸ have found it especially useful in helping women to achieve conception—"for example, in the timing of intercourse, the arrangement of leave for Service people, and in artificial insemination." It requires the co-operation of the patient, but this is easily obtained in cases of sterility and in-patients who wish to avoid pregnancy but are unwilling to practise contraception. Further suggested uses for it are as a test of early pregnancy, in evaluating treatment intended to stimulate ovulation, in timing the date for endometrial biopsy, and in searching for early ova. Tomkins believes that it should also prove of value in studying irregular uterine haemorrhage and in assessing the reliability of contraceptive measures.

BOARDING SCHOOLS FOR THE HANDICAPPED

It is now generally admitted that every child has a right to the education of which he is capable of taking advantage. This principle underlies the new Education Act, but its practical achievement is presenting difficulties which are, or appear to be, almost insoluble, especially in these days when the building industry must devote all its energy to the provision of bare shelter for the ordinary citizen. In the larger cities something has already been done by establishing special schools for those subnormal children who cannot fit into and who cannot take advantage of the ordinary elementary school. All who are concerned with such children in rural areas agree, however, that almost nothing has been done for them. True there are some 36 boarding schools at present accommodating 3,650 children, but only 10 of these, housing 1,300 children, are permanent and provided by local authorities; and it is estimated that, where there are no day special schools, boarding places are needed for 4 per thousand registered pupils, and where day-schools exist 2 per thousand. In addition it is very necessary to provide for the boarding of many maladjusted children referred before or after they come into the juvenile court, whether because of their own asocial behaviour or because their parents for one reason or another cannot arrange for their care and control. Most of these will have to be lodged in hostels, which authorities are agreed should not contain more than 20 children. From most of these hostels the children should attend ordinary schools and a child guidance clinic. The schools, whether for subnormal or for maladjusted children, will also have to be small.

The Ministry of Education's circular No. 79 deals solely with bricks and mortar, and urges local authorities to combine to acquire large houses which, with or without the additional provision of prefabricated huts, can be easily adapted for the purpose of residential schools. This may be done by joint education authorities or by one authority initiating the school and receiving children from neighbouring authorities, but it is pointed out that, however achieved, the need is urgent. The problem is certainly complex, for in these two large groups there are so many subgroups that call for separate consideration and treatment; as, for example, the spastic paralysis cases among the subnormals, the need for whose very special physical and mental education is being demonstrated by the all-too-small and handicapped unit at St. Mary's L.C.C. Hospital, Carshalton. The provision of buildings is, however, not enough, and although the new circular does not go beyond this it is to be hoped that the necessity for a carefully chosen and specially trained staff will not be lost sight of, and that neither central nor local authorities will be content to sit back when they can show in their annual reports that a statistically satisfactory number of handicapped children have been given

lodging, without recording what may happen to the lodgers when they are lodged. Progress in social services is certainly being made, and this is indeed gratifying, but the public must watch carefully and see that this progress is on a real and solid basis and not merely a compilation of plausible figures.

CONTROL OF DANGEROUS DRUG TRAFFIC

During the war years there has been considerable delay in furnishing returns of the production and consumption of dangerous drugs to the Advisory Committee of the League of Nations. The latest information vouchsafed, in a recent report by the Advisory Committee, is for the year 1940. Indeed, some Governments which are large producers, manufacturers, and consumers of opium and other narcotics have failed to supply returns under the Opium Conventions of 1912 to 1936. Thus a world review of the international trade is rendered impossible, and would be largely vitiated by the exchange rates of currencies in many of the countries which are parties to the Conventions. Only 34 countries and territories out of some 70 had in 1941 supplied the Secretariat with returns for 1940.

It is noted that addiction to narcotic drugs is not prevalent in the United Kingdom. Of the 505 addicts reported in 1940, 251 were men and 254 women, 80 were members of the medical profession, 3 were dentists, 5 pharmacists, and 2 veterinary surgeons. Heroin is the drug mostly used by addicts. In India codeine is now included with other alkaloids for control of illicit use. China is striving after "absolute suppression of the drug evil," while in territories occupied by Japan all such efforts have been frustrated and illicit traffic and opium-smoking encouraged. In the Shanghai national settlement opium addiction is widespread and promoted by Korean pedlars in heroin. In Aden opium, ganja, and bang within limits are sold freely to addicts. In Syria and the Lebanon 1,952 kg. of opium and 728 kg. of hashish were seized in 1940, while the police destroyed Indian hemp equivalent to 800,000 kg. of prepared hashish. In Iran the area under the opium poppy nearly doubled in 1940, and some 790,000 kg. of opium were produced. The Permanent Central Opium Board is fully justified in urging that international control of the traffic in narcotics, so far from being relaxed, needs vigilant reinforcement and supervision. That national control is tightly maintained in the United Kingdom can be seen from the report for 1944 just issued as a cyclostyle document by the Home Office.

A first interim report by the Committee on Dermatology set up by the Royal College of Physicians in July, 1945, is concerned with a comprehensive dermatological service and it outlines the facilities required—i.e., numbers of beds, medical personnel, and ancillary services. In a national scheme the demands on the skin departments would be greater than now, as more patients would be referred by practitioners and more would wish for specialized advice. The number of beds available is small and insufficient to cope with the long waiting lists. Effective management of many of these cases, though they are not acutely ill, implies as much nursing care as the average medical case, and this is not obtainable in the patient's home. The report assumes that the country will be divided into regions for the purpose of organizing and maintaining a service of dermatology, the centre of each region being situated in, or attached to, the skin department of a university hospital (or, in London, of a teaching hospital), under a full-time head of professional rank. The report presents a scheme for a national service on this basis, with secondary and peripheral centres. The rehabilitation centre for skin cases is important, but this must at first be experimental.

OCCUPATIONAL EYE DISEASES

BY

JOSEPH MINTON, F.R.C.S.

Major, R.A.M.C., Ophthalmic Surgeon, Hampstead General Hospital, Queen Elizabeth Hospital for Children, Assistant Ophthalmic Surgeon to West End Hospital for Nervous Diseases
(From the Department of Industrial Ophthalmology, Royal Eye Hospital, London)

Ophthalmologists and other medical men not connected with industry often forget to inquire into the occupational aspect of disease. In the diagnosis and treatment of eye injuries and diseases it is most important to bear in mind the nature of the patient's occupation. For instance when one examines a patient who complains of a piece of metal flying into his eye it is necessary to ascertain whether he was grinding or hammering at the time of the accident. A grinder gets a superficial corneal foreign body which is easily removed, but a history of hammering, chipping, boring, or milling should make the industrial medical officer and the ophthalmologist beware of the possibility of an intraocular foreign body. When we treat acute or chronic conjunctivitis or keratitis it is most important to bear in mind the likelihood of an occupational cause. Obscure cases of retinitis, retrolental neuritis and ocular palsies, and amblyopia should always make us think of a possibility of chronic poisoning arising from industrial solvents, etc.

Acute and Chronic Keratitis—Rankine (1936) reported that 1,598 workers suffering from a superficial punctate keratitis were seen in the course of two years in an artificial silk factory. The patients complained of blurring of vision, pain in the eyes, headaches, lacrimation, and a feeling of grittiness. It was found that H₂S (hydrogen sulphide) which is present in the air in the acid house in the artificial-silk industry, was responsible for the onset of the keratitis. McDonald and others have shown that the presence of 10 parts in a million of hydrogen sulphide in the air is sufficient to cause a keratitis. Improved methods of ventilation have now reduced considerably its incidence in the artificial-silk industry. The same type of keratitis, also due to hydrogen sulphide, is known to occur in the sugar industry. Workers in furniture trades, metal industries, and straw hat factories occasionally develop keratitis. It is most probably due to the use of benzene and similar solvents of varnishes and shellac. The largest number of cases occur in winter months when ventilation is poorest. Bakers often suffer from a chronic blepharitis and conjunctivitis. Agricultural workers are also known to suffer from a keratitis which may be allergic in origin and is due to various weeds (pigweed, redroot, and others) and also peat dust. Lastly, a symptomless chronic occupational keratitis is found in lathe workers, stone-cutters, grinders, and sand-blasters. The cornea of these workers shows bilateral minute regularly shaped scars with glistening foreign bodies embedded in them. There are also a number of multiple corneal erosions which stain with fluorescein (Davidson, 1939). The sensitivity of the cornea is usually greatly diminished. Many of these cases of keratitis will be diagnosed as acute or chronic conjunctivitis unless the cornea is examined with a slit-lamp microscope.

Lens Opacities—In 1908 Sir Thomas Legge, on examination of 513 workers engaged in the glass industry, reported that 20% of them had lens changes. A committee established by the Royal Society in the same year considered that these lens opacities were due to infra-red rays. They are found in the posterior cortex of the lens. The same lenticular changes are also seen in furnace workers, and some authorities have stated that 17% of these workers show posterior cortical lens changes. It takes 10 to 20 years of work in these industries for these lens changes to develop. The provision of protective goggles for glass workers has considerably reduced the incidence of lens opacities in the industry. Furnace workers are still inefficiently protected.

Industrial Poisons

The most important of these poisons are lead derivatives of benzene, carbon bisulphide, methyl alcohol, arsenic and its derivatives, carbon tetrachloride, and trichlorethylene. These and many other toxic substances used in industry may produce toxic amblyopias, optic neuritis and ocular palsies.

Methyl alcohol is used as a solvent for shellacs and varnishes, in the preparation of perfumes, paint removers, as a solvent for aniline dyes, and in toilet materials. Inhalation of vapour may cause optic neuritis and ocular palsies. Painters working in closed spaces use the fumes of methyl alcohol, and among them optic atrophy has been reported.

Carbon bisulphide is used in the rubber industry, in the artificial silk industry, and in refrigerating plants. Inhalation of the vapour causes amblyopia and optic neuritis, often a bilateral symmetrical appearance, mental disturbances, and general mental confusion.

Lead poisoning may occur in composers, pumbers, accumulators makers, makers of lead pipe, and paint grinders. It causes optic neuritis and ocular palsies.

Arsenic is used in the manufacture of artificial fibres and insecticides, the dyeing industry, pickling, etc. Ocular palsies have been reported. Cosmetics which have some form of arsenic may cause eczema of the eyelids.

Carbon tetrachloride is employed as an industrial solvent, in dry cleaning, etc. Many cases of loss of vision resulted from use of this substance. The loss of the peripheral field is the most prominent feature of this type of amblyopia.

Trichlorethylene is used as a degreasing agent in dry cleaning, etc. It may cause optic neuritis and retinitis.

Benzol and its derivative dimethylbenzol are used in the manufacture of aniline dyes, in dry cleaning, in the manufacture of varnishes, in vulcanizing rubber, and in other industries. The inhalation of the vapour of these substances causes optic neuritis.

Department of Industrial Ophthalmology

To deal with all these problems of occupational eye diseases and eye injuries in industry the Royal Eye Hospital has decided to establish a department of industrial ophthalmology. The ophthalmologist is not usually acquainted with the methods of production used in various industries. He therefore should have the assistance of skilled engineers, safety officers, and makers of preventive appliances to advise him on technical problems. I am fortunate in having secured the help of an expert engineer and safety officer and two representatives of makers of safety appliances. These form a committee which sits with me every Wednesday afternoon. When a patient is referred to me I ask him how he injured his eye, or if there is no history of injury, whether there are any circumstances or conditions at his work which could have caused an inflammation of the eye. He relates the history of the injury, amplifying it with technical details. The members of my committee question him on safety appliances used and explain to me the technical problems. The patients often call this "a court of inquiry."

The largest numbers of cases referred to the department are of course those of corneal foreign bodies from grinders' stones. These patients attend in hundreds every week, and include juveniles from the age of 14. We inquire whether protective appliances were supplied. Many unreasonable, and at other times legitimate objections are given by the workmen against the use of goggles. One lad of 14 objected to wearing goggles which had also been worn by other workmen, he considered it unhygienic. We felt that this was a most reasonable objection and provided him with a suitable pair of goggles for his own use from a stock given to us by various firms. Goggles generally do not provide complete protection, and a good screen or guard fitted to the machine is very much more effective. The provision of such a screen by employers is encouraged. If goggles are provided they must be comfortable to wear. We encourage further research into the production of efficient and comfortable goggles, suitable for various forms of work. Letters are written to the employers of workmen who have attended at this hospital and advice is given on the best means of protecting the workmen's eyes. In many cases the employers have been most co-operative.

Ocular Affections due to Welding

We have dealt with a number of injuries to the eye resulting from electric welding. Welders working with the electric arc often get an "arc eye." This may be due to inefficient protection or to the fact that the welder has not brought the helmet or the screen in front of his face soon enough after striking the arc. Many welders are negligent, they adjust the arc without the shield, and it is only after the arc is struck that the shield is put on. An "arc eye" will follow. The welder's mate may also suffer from "arc eye" from the same cause. Welders often work in workshops which are not screened, and fitters in

the vicinity get an "arc eye." Anyone who exposes his eye to the welder's arc will develop symptoms within about six hours. The eyes begin to burn and are painful. The patient complains of photophobia and lacrimation. He is suffering from a conjunctivitis, and if the reaction has been due to a prolonged exposure he will also have a mild superficial punctate keratitis, with multiple staining areas of the cornea. The best treatment in such cases is instillation of gutt. adrenalin. 1 in 2,000 and a mild analgesic—holocaine 1% or pantocaine 1%. Cocaine should never be used, as it is injurious to the cornea. Cold applications or iced compresses are advisable. The acute condition subsides within a day or two. It has been generally held that welders suffer only from an acute conjunctivitis—an "arc eye" which leaves no further complications; but my experience has shown that repeated exposure to the welder's arc causes a chronic keratitis.

I have recently seen at the hospital a number of welders with a *chronic superficial keratitis*. The cornea of these men had multiple erosions, many of which stained with fluorescein. The patients complained of blurring of vision, grittiness, and a certain amount of photophobia. The conjunctiva remained white in several cases. On investigation it was found that in many instances the protective screens were faulty and allowed transmission of the dangerous radiations from the arc. Welders' screens therefore should be regularly (almost daily) inspected by safety officers. Welding should be done only in welders' booths and not in open workshops. This will prevent many cases of "arc eye" and chronic keratitis in fitters, who often have to work in close proximity to welders.

Chronic Conjunctivitis and Keratitis.—In the department of industrial ophthalmology I had many cases of chronic conjunctivitis referred to me. On investigation it was found that many of these patients worked in dusty workshops with inefficient ventilation. One man, a wood-cutter, was continually exposed to wood dust, which caused a chronic conjunctivitis. He was advised to wear goggles at work, when his condition quickly cleared up. Another patient, suffering from chronic conjunctivitis and a mild keratitis, was working in a mica factory. Mica dust was responsible for her condition. A change of occupation was followed by complete cure. Many similar cases could be quoted.

Several obscure cases of retinitis have been referred to the department. Some of these patients were engaged in welding operations; others were panel-beaters and sheet-metal workers using poisonous degreasing substances (such as trichlorethylene, benzene, paraffin). These cases are still being investigated to exclude a possible occupational cause for the retinitis.

Conclusion

This search for "occupational causes" is, in fact, all-important. Whenever a case of eye disease is being investigated we not merely should search for a "septic focus" but should always inquire into the working conditions.

The establishment of departments of industrial ophthalmology is essential. Such a department at one eye hospital could deal with cases referred from other eye hospitals and ophthalmic departments of the general hospitals. We would thus ensure further success in the fight against occupational injuries and disease.

The annual report for 1945 of the Manchester, Salford, and Stretford Joint Hospitals Advisory Board puts forward a scheme for the establishment of a co-ordinated psychiatric service. The University of Manchester has been asked to consider setting up a chair for psychiatry, and the new professor would be responsible for all teaching. Provisionally, 150 beds should be provided at six of the existing municipal and voluntary hospitals. Each hospital should be able to give out-patient, in-patient, and "follow-up" services, and the whole scheme should be linked with child guidance clinics. The service proposed in this report would cover a population of approximately one million in and around Manchester, but could be extended later to cover an area much wider than that of the Joint Board.

THE FUTURE OF HOSPITAL SERVICES

(Continued from p. 141)

SURVEY OF NORTH-WESTERN AREA

The Ministry of Health Hospital Survey was undertaken in the north-western area—including Lancashire, Cheshire, and North Wales, and Cumberland and Westmorland—by Sir Ernest Roe Carling and Dr. T. S. McIntosh.* The surveyors, while making no reflection on the work done in the hospitals in this region have many criticisms of the hospital buildings, which, generally speaking, fall far short of a satisfactory standard. The bulk of them were put up in late Victorian times, and outside Manchester and Liverpool they are small and usually situated in the central and noisy parts of towns. The municipal general hospitals are, almost without exception, converted Poor Law institutions and are attempting to perform a function for which they were not designed.

In some parts of the area a shortage of beds is apparent, and a considerable hidden shortage is brought to light whenever a good new service is established. The demand for maternity beds is steadily rising and only partially met. The accommodation for sick children falls far short of need. Provision for medical (as distinct from surgical) cases in voluntary hospitals is disproportionately small. There is a marked shortage of beds for tuberculous patients. Accommodation for private patients is inadequate.

"We hope that the hospital authorities will regard it as part of their duty to the community to provide for these patients and that they will do so in the hospital most suited to the purpose, without regard to whether it is municipal or voluntary."

Specialists are unevenly distributed. Their presence or absence in a locality is apt to depend upon its distance from Manchester or Liverpool. Representatives of the more restricted specialties are to be found only in the main centres. The surveyors agree that highly specialized work, such as neurosurgery and plastic surgery, must be concentrated in such centres but the common specialties and also the intermediate ones, such as genito-urinary and orthopaedic surgery, should be distributed so far as practicable, both to provide service within easy reach of patients and to take some of the burden of outside work of the two university cities.

The Problem in Lancashire

In Lancashire and Cheshire the surveyors have mapped out twenty hospital districts, each of which is or could conveniently be served by a single general hospital, and then have combined them into six administrative areas—North, East, and Central Lancashire, Manchester, Liverpool, and the greater part of Cheshire. Even in the most extensive of these twenty districts—the one based on Preston, with a population of a quarter of a million—the most remote part is only 16 miles from the centre. Most of these districts are considered to require at least one physician, general surgeon, obstetrician and gynaecologist, ear-nose-and-throat surgeon, and ophthalmic surgeon. The specialist staff should be appointed to the district rather than to the particular hospital, and play an important part in the clinical services.

In the opinion of the surveyors, Liverpool hospitals, considered as premises, fall far below a satisfactory standard. The provision, both general and special, requires a general overhaul and comprehensive replanning. A very formidable building programme will be necessary. A new teaching hospital of about 1,000 beds is required.

Of Manchester Royal Infirmary the surveyors say that although built only in 1909 it is already out of date in some respects, though it is still a "good hospital physically." At the reputation of its staff and services gives it a dominating position in the whole area. The encouraging start of co-operation between the Manchester city council and the voluntary hospitals is noted, but co-operation should be speeded up into a firm partnership. Sympathetic consideration should be given

* *Hospital Survey. The Hospital Services of the North-Western Area*. London: H.M. Stationery Office. 1945. (10s. net.)

to the "island site" scheme—a 70 acre area zoned for hospital purposes by the town planning authority and approved by the Joint Hospitals Advisory Board

Cheshire and North Wales

The large Cheshire district based on Crewe with a population of 180 000 has nothing but cottage hospitals and public assistance institutions. A similar district based on Chester has an important and busy voluntary hospital—the Chester Royal Infirmary—giving a wide range of services notwithstanding old buildings and insufficient accommodation. The municipal hospital at Chester is developing its service but cannot do much more without substantial rebuilding. A scheme of improvement and extension increasing the Royal Infirmary beds by 100, has been prepared, but the surveyors prefer the erection of a new hospital.

North Wales is poorly provided with hospital services. Taking both building and staffing into account there is at present no general hospital of the requisite size and quality. New buildings are urgently required, but the need for settling a specialist team in the area is even more urgent. Such specialists will to a great extent need to be paid otherwise than by private fees. The surveyors favour a new hospital at Bangor to serve the counties of Anglesey and Caernarvon, while the counties of Denbigh and Flint would be served by a hospital or hospitals at Wrexham and one to be provided at Rhyl or St Asaph. Wrexham and Chester could work mutual advantages, work in association and share certain members of staff.

The institutional treatment of tuberculosis in Lancashire and Cheshire, in the opinion of the surveyors should be part of a comprehensive hospital service, institutional care should be kept in as close relation as possible to dispensary and domiciliary provision and the preventive and social side of the work and the tuberculosis officers of the area should form a team for carrying out both dispensary and institutional work. They favour a scheme on the lines of that already devised by the Lancashire county authority, but with the important difference that the dispensary areas would include the county boroughs as well as county districts.

Anglo-Scottish Partnership Proposed

At Carlisle the surveyors found a much more comprehensive group of specialists than was to be expected in a town of the size. Cumberland, however, is very badly off for hospitals of all kinds. There is a marked deficiency of beds for surgical cases, both general and special, and the position is still worse for medical conditions and for maternity. On the other hand, Cumberland presents a very good example of three party co-operation—the Carlisle city council, the Cumberland county council and a voluntary hospital, the Cumberland Infirmary.

"In our view it is most desirable that Carlisle should be developed into a centre as complete in its range of services as is practicable, and should aim at a status intermediate between that of a university centre and that of the ordinary hospital district."

It is understood that the Scottish surveyors are recommending that Dumfries, 33 miles from Carlisle, should be a hospital centre based on Glasgow. The surveyors for the North-Western Area consider that Dumfries might find it convenient to make some use of Carlisle's staff and facilities. Indeed, a Carlisle-Dumfries partnership would be a good thing, and a combined population of over 400 000 in North West England and South West Scotland would be served. The fact that the two partners would be based on different university centres—Newcastle and Glasgow respectively—need not be an obstacle. Newcastle is undoubtedly the university centre with which Carlisle should be associated. A further recommendation is that a new general hospital should be built in West Cumberland and the remainder of Cumberland and North Westmorland should be served by Carlisle.

SURVEY OF SOUTH WALES AND MONMOUTHSHIRE

The South Wales and Monmouthshire area has been surveyed by Dr A. Trevor Jones, Prof J. A. Nixon, and Prof R. M. F. Picken. There are nearly two million people in this region,

more than half of whom are crowded into the county of Glamorgan. In the mining valleys the miners largely finance their own hospitals, and prefer these small hospitals to one in a large town or centre some distance away. The surveyors stress upon the great advances which have been made in hospitalization in South Wales during the past forty years. Many hospitals large and small, have been established during that period and others have been extended and improved. The number of hospital beds is 9 423 or 4.9 beds per 1 000 of population. Only in five out of 56 "acute" general and special hospitals are specialists in continuous charge of patients. The five hospitals are all large and in theory are headed by the available hospital beds are under the supervision of practising consultant rank, although in only a minority of the centres close and continuous.

"There are many advantages both to the patient and to the doctor under a system whereby routine work (at hospital) is done by general practitioners. The patient has his own chosen doctor to care for his well being his personal history is well understood by the medical and nursing staff and there is continuity of supervision after discharge from the hospital. We think that this system has had a stimulating effect on the work of the general practitioner, has enhanced his keenness, and kept him abreast of modern developments."

Very little has been done in South Wales to face the problem of the chronic sick. For these patients the worst and oldest buildings are set aside. The inevitable opinion of general practitioners is that there is great need for establishing institutional accommodation for such cases. "It is impossible to overstate the distress, discomfort, and strain which the absence of proper accommodation for the chronic sick involves for the patients and for their relatives." The surveyors were dissatisfied with the standard of medical treatment given to chronic cases even in those institutions at which specialist advice is available. Difficulties of treatment are increased by the haphazard mixture of cases which find their way into the chronic wards. As for isolation hospitals most of them are too small to carry out economically the medical staff required not constructed to permit segregation of cases, and except in the county boroughs not part of a large hospital organization so as to insure the benefit of economic management and common purchasing. Praise is given to the antenatal services of South Wales but maternity wards are overcrowded.

Adequacy of Medical Staff

All the 18 men who confine themselves to specialist practice in general surgery in this area are in responsible charge of beds in Cardiff, Swansea or Newport. The number of hospitals visited by individual surgeons varies from one to as many as nine. The small number of surgeons and the multiplicity of hospitals they attend raise a doubt in the minds of the surveyors whether the best surgical skill is being made regularly available to all patients. The employment of consultant physicians is even more restricted outside the three towns named, only 19 hospitals are regularly visited by a consultant physician. A great demand exists for the consultant facilities afforded by hospital out-patient departments, but the provision has not kept pace with the demand.

In the view of the surveyors no area general hospital or combination of hospitals should be without the constant attendance of at least one general physician, general surgeon, obstetrician and gynaecologist, anaesthetist, radiologist, and pathologist, with less frequent attendance by other specialists. This means a subsidized distribution of specialists but in making such distribution attention is called to the dangers of segregation away from large centres and from contact with colleagues. Something might be done to meet these dangers by the appointment in an advisory capacity of a few peripatetic specialists of great experience and high reputation as in the fishing service, and in the E.M.S. In any case, area appointments away from the centres should not be unduly prolonged without interruption.

While they deprecate any wide practice of major surgery by general practitioners, the surveyors recognize that it is necessary to give an opportunity to practitioners who have carried out combined special and general practice and who satisfy reasonable criteria to join the ranks of specialists, if they so desire on satisfactory economic and other terms. Reports of Societies

CLINICAL IMPLICATIONS OF DISABLEMENT ACT

At a recent meeting of the Section of Physical Medicine of the Royal Society of Medicine Dr HAROLD BALME read a paper on the clinical implications of the Disabled Persons (Employment) Act, 1944. He mentioned that the register of all persons substantially handicapped, which the Act requires to be compiled is expected to include when completed not fewer than a million to a million and a half names of people who will have the right to claim assistance in rehabilitation and industrial resettlement.

Dr. Balme indicated the directions in which medical assistance will be essential in the successful operation of the Act. He summed them up in the phrases, prevention of residual disability; assessment of loss of functional capacity, and periodical follow-up and review. Certain well established principles had he said, emerged from war experience which should be of the greatest value in making plans for the development of hospital rehabilitation as an integral part of future health services.

(1) *Continuity of Medical Supervision*—Rehabilitation was an essential part of treatment itself and should therefore be prescribed by the physician or surgeon in charge of the case, who should maintain close supervision of the patient's progress both in the in- and out-patient departments and if possible at the residential rehabilitation centre.

(2) *Range of Medical and Surgical Disabilities suitable for Active Rehabilitation*—Active rehabilitation was applicable to much more than orthopaedic disabilities and traumatic surgery. Its principles applied to all forms of medical and surgical disability or loss of physical and psychological function resulting from prolonged immobilization or severe illness.

(3) *Appointment of Trained Staff*—The provision of an adequate hospital rehabilitation service was not a matter which could be safely left to the haphazard devices of any physiotherapist who happened to have been practising massage and electrotherapy there for a course of years. It could be properly entrusted only to a trained staff thoroughly conversant with modern methods, and such staff should wherever possible have a specialist in physical medicine at its head.

(4) *A Balanced and Progressive Programme*—If rehabilitation was to be carried out scientifically it was essential that a carefully thought out programme should be laid down for each type of medical and surgical disability and for each successive grade in the process of recovery, the initial states in the wards, and out-patient department, and the later stages, if possible, away from the hospital atmosphere.

(5) *Care of Psychological Factor*—If rehabilitation was to constitute an integral part of future hospital services the almoner's department must be strengthened in every hospital (or established if not already in existence), and these social workers must be set free from much of the routine financial work which at present absorbed their time.

Assessment of Functional Capacity

A further duty laid upon hospital services in implementing the Act consisted in the provision of scientific guidance as to the exact functional capacity of any patient who would never be able to return to his former occupation. The actual responsibility of finding suitable work for such a man rested with the disablement rehabilitation officer attached to all the larger employment exchanges, but such an officer had no knowledge of medicine or surgery, and must work in the dark unless carefully instructed by those who had direct knowledge of the patient's physical condition and the extent and character of his disability. To express such disability in abstruse medical terms was of little use, what the resettlement officer needed was a clear report stating just what the disabled person could and could not do and what environmental conditions would be prejudicial. Such a report could be supplied on the D.P. 1 Form issued experimentally by the Ministry of Labour, but the ideal method was not by certificate, it was by regular conference between representatives of the hospital and of the employment exchange. A model system had been started at a large local authority hospital near London. All cases in need of rehabilitation were referred to the specialist in physical medicine, who directed their programme of activities and who had been provided with his own almoner for dealing with the personal problems of each patient. A conference was held weekly by this medical director of rehabilitation, the almoner, and the local D.R.O., when each patient likely to require vocational training

for some new occupation was brought under review and explicit recommendations as to suitable work were thus based upon the medical officer's intimate knowledge of the man's disability and functional capacity, the almoner's knowledge of his personal circumstances, and the D.R.O.'s knowledge of available jobs or courses of training.

Careful supervision and periodical review were still necessary for the successful performance by the disabled person of his new task and in many cases this supervision would be maintained by an industrial medical officer. But it was the hospital which actually treated the patient and saw him through to the point at which he was fitted for a new job which always ought to take the initiative in follow up.

In conclusion Dr. Balme mentioned four types of medical rehabilitation centres which should be provided among the facilities for rehabilitation referred to in the White Paper, the basis of the Industrial Injuries Bill.

(1) An efficient physiotherapy department at every hospital sufficient to give proper rehabilitation to all in-patients.

(2) A general outpatient rehabilitation centre in every town or district, capable of treating patients attending the casualty or outpatient departments of the local hospitals.

(3) Residential rehabilitation centres for patients requiring long stay rehabilitation.

(4) Special rehabilitation centres for particular disabilities.

He added that the Ministries of Health and Labour were now providing an intensive six-months course in medical rehabilitation for selected physical training instructors released from the Forces, of whom 150 should be available in the next twelve months. But the greatest need would be the inclusion of regular instruction in rehabilitation as part of the ordinary medical curriculum, and the integration of this important development in social medicine in the education of all future doctors.

PITFALLS IN PULMONARY DIAGNOSIS

In an address to the Manchester Medical Society on some pitfalls in the diagnosis of pulmonary disease Dr R. ELLIS said that the earliest detection of tuberculosis usually defied clinical examination. Even in some advanced cases with deep-seated cavities the physical signs might be virtually absent or at most suggest much less disease than actually existed. Only x-ray examination could reveal the disease in its earliest stages. A diagnosis of chronic bronchitis in young persons was risky because there was often a more gross underlying pathology. In a number of Service cases in which this diagnosis had been made bronchiectasis was found more often than either the physical signs or x-ray appearance of the lungs would suggest. Bronchograms in some of these cases showed bronchiectasis to the extent of which seemed to bear some relation to the degree and frequency of the "bronchitis." Bronchial carcinoma presented special difficulty in early diagnosis, because there were often so few symptoms in the early stages that the patient did not seek advice in time to benefit from lobectomy or pneumonectomy. Some of the more chronic cavitating neoplasms of lung might simulate chronic lung abscess. Misleading histories could lead to errors in diagnosis by misinterpretation of the physical signs. One patient who gave a history consistent with spontaneous pneumothorax and who had physical and x-ray signs resembling high pressure pneumothorax actually had a very large cyst of the left lung. Another described symptoms of acute bronchial obstruction, which by exclusion, was considered might be due to a bronchial papilloma. Bronchoscopy revealed a papilloma, but necropsy showed that this papilloma was the distal end of a large bronchial carcinoma which had grown down the main bronchus to the hilum.

Dr Florencio Bustiza, professor of plant physiology at the University of Madrid and president of the Microbiological Section of the Royal Academy of Pharmacy in Madrid, has left for Spain on the conclusion of a short visit to Britain, after a tour of the U.S.A., to gather information about medical research work. He was born in England, where he received his early education. Dr. Bustiza, who has lectured and written extensively in Spain on British medical discoveries, including penicillin, came, among others, Sir Alexander Fleming, Sir Howard Florey, and Dr. Chaun. He visited the London School of Hygiene and Tropical Medicine, the National Institute for Medical Research, the Wellcome Research Institute, the Lister Institute, the Imperial Cancer Research Institute, the Botanic Gardens, Kew, and the John Innes Horticultural Institute. He was entertained to lunch at the House of Commons by Mr H. N. Linstead, M.P., secretary of the Pharmaceutical Society of Great Britain.

Correspondence

Principle and Unity

SIR,—In your restrained and helpful leader (Feb. 2, p. 167) you speak of the Socialist Medical Association being "content with nothing that stops short of the socialization of medicine." May I enter a plea once more for the use of the word "nationalization" rather than "socialization" when we use the term in the sense of "any form of service which leads directly or indirectly to the profession as a whole becoming full-time salaried servants of the State."

As I pointed out in my Cardiff address (*Journal*, March 17, 1945, p. 357), to "socialize" medicine may mean only to make medicine more accessible to the public—an achievement which the public ardently desires and which we all, surely, approve. To "nationalize" medicine can only have the meaning given above. The ambiguity is fostered by the Socialists—I must not say deliberately—and the public is greatly deceived in consequence.—I am, etc.,

London, W.1.

HORDER.

Mitral Regurgitation

SIR,—I was glad to see Dr. Geoffrey Bourne's timely letter on this subject (Jan. 26, p. 143). Twenty-five to thirty years ago most of us remember that mitral regurgitation was a commonly made diagnosis. It led to the error of mistaking many harmless systolic murmurs as evidence of this. Then the pendulum swung until the medical students in some schools of medicine grew up to believe that a systolic apical murmur was never evidence of organic disease. Latterly this view has been modified, as Dr. Bourne has pointed out, and it is now suggested that the murmur, if indicative of organic disease, indicates mitral stenosis. This, as Dr. Bourne points out, is mechanically impossible, however loud or rough the murmur may be (though, of course, mitral stenosis may also be present, but clinically undetectable).

Quite apart from systolic murmurs arising from dilatation of the left ventricle, as in hypertension, myocardial disease, thyrotoxicosis, and so forth, there is much evidence to suggest that the systolic murmur may be the dominant sign of mitral valve involvement by rheumatism. Evidence of this is found, first, in rheumatic heart disease of childhood, where such gross cardiac signs may be present as to leave no doubt that the heart is organically diseased and yet the only murmur is an apical systolic. Moreover, if these cases are watched for several years many of them, indeed one might almost say most of them, do not develop presystolic or diastolic murmurs at the apex. These systolic murmurs are nearly always loud, well conducted, and vary little in their intensity with posture and respiration. These are the signs by which we used to be taught to recognize an "organic" murmur. They are also the characteristics of the systolic murmur when it is combined with an apical diastolic, leaving no doubt as to the diagnosis of mitral stenosis. Is it not justifiable, therefore, to make a diagnosis of rheumatic mitral regurgitation where the systolic murmur alone is present, especially when there is other evidence of organic heart disease such as enlargement and a history of rheumatism? Further, I would suggest that a murmur having these characteristics and not accompanied by other clear evidence of organic heart disease should be regarded with suspicion.

This leads to a consideration of the second group of cases which the apical systolic murmur is of great importance—namely, the ones to which Dr. Bourne has referred in which bacterial endocarditis has supervened. At the heart clinic of the Royal Infirmary we have seen a number of cases of clearly proven bacterial endocarditis following on rheumatic valvulitis, some of which have been treated with penicillin with good response yet with the apical systolic murmur the sole murmur before and after treatment. It would be unfortunate if Dr. Bourne's or this letter gave the impression that most systolic murmurs signified mitral disease. The majority do not, but it is essential for the student to be aware of the possibility of an apical systolic murmur pointing to organic cardiac disease. Perhaps a suitable division of systolic murmurs would be into "significant" and "insignificant." Significant murmurs at the apex would include those caused by left ventricular dilatation

and those caused by organic changes in the mitral valve cusps. Both could be styled mitral regurgitation, but it would be wise to qualify the diagnosis by the description of the cause; e.g., mitral regurgitation—rheumatic carditis, or mitral regurgitation—hypertensive heart disease. Insignificant murmurs might include those due to temporary disturbance in the size of the valve ring, as in fevers and anaemias, causing a mitral regurgitation which will disappear with treatment, and also a whole host of systolic murmurs which have no pathological significance at all. These will include murmurs that vary in intensity with posture and respiration, are not usually loud and rarely conducted, and are free from association with any other signs of cardiovascular disease.

Such a classification, though a trifle dogmatic, might help the student to clarify his ideas on a subject in which teaching has unfortunately differed so much in the various medical schools—I am, etc.,

E. NOBLE CHAMBERLAIN.

Juvenile Delinquency and its Remedy

SIR,—The view expressed in the annotation (Jan. 19, p. 94) on Mr. F. W. Skinnard's article that the lack of a suitable occupation is an important (*precipitating*) factor in causing juvenile delinquency will be readily conceded. It is, indeed, but a corollary to the assertion of Basilides in the second century A.D. that the child is only innocent in the sense that it has not had the opportunity to sin. Several other points however, call for criticism.

The "chief point," it is stated, "and one that ought never to be forgotten," is the "fundamental difference" between juvenile delinquency and adult crime. Now this is a statement which can find no support at all in psychiatric research; on the contrary, everything goes to show that most adult crime have their origin in maladjustments of early childhood. Thus it is but a matter of the chronological age at which antisocial acts become manifest. To say that a "child charged with an indictable offence" cannot be "the embryo of the habituated adult offender" because juvenile delinquency is apparently on the increase whereas adult crime is not is no valid argument for the following reasons.

1. As you remark, the increase in persons under 16 charged with indictable offences (which is not the same thing as an increase in the number of delinquencies committed) was noticeable after the passing of the Children Act, 1908, and, especially of the Children and Young Persons Act, 1933, the public and the police becoming less reluctant to charge children with offences after special provision had been made for dealing separately with such cases; also the younger the offender the easier as a general rule is the detection of the offence (Cf. Carr-Saunders *et al.*, *Young Offenders*, 1942, pp. 43 ff. *Criminal Statistics*, 1934, pp. viii-ix, xiii-xv.)

2. The fact that the "vast majority of adult criminals have no police record as children" does not mean that they did not commit any antisocial acts; "the number of offences actually committed by children is vastly greater than the number of charges brought" (*Criminal Statistics*, 1934, p. xiv); this is all the more significant if we recall that many adult criminals were children before the passing of the special Acts, and thus were not charged and had no police record. Also, it is well known to psychiatrists that it is largely a matter of chance whether a child's maladjustment to society first manifests itself in antisocial acts which transgress definite laws, or in neurotic traits, educational difficulties, etc. (The mind cannot differentiate as clearly between these two forms of maladjustment as does omniscient society.)

3. Evidence confirming the relation between adult and juvenile crime is afforded by a recent English survey, stating that "there was found to be a relationship between the juvenile and adult crime rates—i.e., when of two counties with the same urbanization index one had a higher juvenile crime rate, its adult crime rate was usually higher, too" (Carr-Saunders, p. 49); and by an American study of the adult prison population in 1930 where it was found that 54.8% had been less than 21 years of age when committed (Barnes and Teeters, *New Horizons in Criminology*, 1944, p. 111).

4. Recent work has shown the importance of the factor of emotional and social maturation in controlling the course of

"Cord Round the Neck"

SIR.—In the course of attendance on about 5000 confinements I have never seen a stillbirth which I could ascribe to the above cause. I think it is a possible cause in the absence of a medical man or a trained midwife, but not otherwise. On one occasion I feared the child would be strangled so I cut the cord at once. The cord was twice round the neck and taut from the navel to the neck and from the neck to the placenta. The child had been shot out suddenly, so that there was an extra pull on the cord. I was unable to get my fingers underneath it. I am inclined to agree with Mr Mortimer Reddington (Jan 19, p. 109) that such a diagnosis should be regarded with grave obstetric doubt—I am, etc.,

FRIDAY

ROBERT ANDERSON

Medical Future of the Colonies

SIR.—I have just received the *Journal* of Nov. 17, 1945 and in view of the Commission on Salaries inquiry in the West African Colonies appointed by the Secretary of State for the Colonies to start early in Jan., 1946 I read with great interest the leading article on the medical future of the Colonies (p. 693). On reaching the first sentence of the concluding paragraph I received a shock. "These reforms are suggested only for the European medical officers." This at once raises the racial question with its unscientific invidious treatment meted out to the non-Europeans in the services of the different British colonies. Does the B.M.A. support this distinction based on "colour"? Does the B.M.A. hold no brief for its non-European members who are employed by the British Colonial Governments?

I may claim to some extent to be representative of the non-European medical officers in the Colonies in general and of Sierra Leone (West Africa) in particular, having just retired after 32½ years' service in the Sierra Leone Medical Service as distinct from the Colonial Medical Service. I have been a member of the B.M.A. since 1912. Why should this editorial deal with the grievances of only one part of its members pointedly? Non-Europeans equally with their European colleagues are entitled to all the facilities of the Association and to the help of the B.M.A. in the alleviation of their legitimate service grievances.

Can it be, then, that the writer seriously considers that we have no grievances or that they are too trivial to be considered? Very early in the article it is stated "It is no exaggeration to say that before this war most people were profoundly ignorant of conditions in this Empire." This persistent overlooking and ignorance of the non-European civil servants in the Colonies is one of them.

The purport of the rest of this letter is to show very briefly the invidious distinctions and inequalities of conditions of service between European and non-European medical officers in one Colony—Sierra Leone—since the formation of the West African Medical Service by Chamberlain in 1902. Prior to this since 1865 African medical officers had been continuously in Sierra Leone, frequently in those early days half or two-thirds of the medical staff were African, receiving the same pay and promotion as their European colleagues. In the 'seventies one was head of the medical department of the Gambia with a junior European under him and in the 'nineties a similar state existed on the Gold Coast. The Africans had all been trained in the medical schools in the U.K. and passed the same (frequently higher) examinations and been registered in exactly the same way as their European colleagues.

With the formation of the W.A.M.S. the colour bar was introduced and no West African could enter the West African Medical Service. Thus there were two services side by side—the W.A.M.S. (European) and the local Colony service (African). In 1943 the W.A.M.S. was absorbed into the larger Colonial Medical Service, and though in the more recent advertisements for recruits in the medical press and the official regulations no mention is made of it the colour bar still exists, as so far no non-European has been appointed to West Africa and African applicants have been offered posts in the local Colony services. Thus there are still two services. So, regardless of what policy may in the future be adopted towards the training of medical men from the indigenous peoples, there is at present a definite body of non-European personnel in the

West African Colonies (three hold specialist posts and areas have been awarded the M.B.E.), and they cannot be passed over so easily. Not only were these non-European medical officers on a much smaller salary scale, but until quite recently there was no promotion for them from the grade of medical officer and though qualified they were not employed on the health side. In addition their European colleagues have the following privileges all of which have a definite colour line: longer vacation leave and local leave with expenses paid on the way; good furnished quarters, or an allowance in lieu; free conservancy when in Freetown; the capital, free power, water supply, and exemption from municipal rates; per diem on a higher scale and if re-employed when on per diem receive an additional 10% and then still have a much longer period of full pay before coming on to half pay.

I have had interviews and correspondence with several of the medical and Dominion secretaries of the B.M.A. since 1922 and have applied for the help of the B.M.A. to redress the above inequalities. On the above facts are on the side in the B.M.A. office—and in spite of this we non-Europeans are passed over—*I am, etc.*

M. C. F. EASON
Sierra Leone Medical Officer (General Practice)

FRIDAY

Medical Journals for Hong Kong

SIR.—Would you allow me the hospitality of your columns to make an appeal on behalf of my colleagues in Hong Kong? Below is an extract from a letter just received from one of the Chinese doctors who remained at his post throughout the 3½ years of Japanese occupation, at my earnest request in order to provide medical and health services for the prisoners of war and civilian internees, their unattended wives, children and dependants, and for the general community. Such men remained loyal to the Allied cause despite every effort by the Japanese military and civilian authorities to win them over with alluring promises of advancement. Hardship, torture, starvation and even imprisonment and all that went with it including mistreatment and loss of health and honour, failed to break their spirit and they courageously carried on their duty even after my removal by the Kempeitai from the island. I quote from one of several similar letters received from the Far East:

"The doctors here are terribly short of medical literature. I would be useful to collect some back numbers of the *Lancet*, *British Medical Journal*, *Practitioner*, *British Journal of Surgery*, etc. that are wanted by our British professional brothers, to be circulated among doctors of the various hospitals. No doubt all of us here in Hong Kong want to know what has happened in the past few years. Honestly we are not jealous at the aid and doctoring and wealth brought back by friends who went away from Hong Kong during the Japanese occupation, but we do want to catch up intellectually with what we missed."

On the receipt of a postcard I shall be very happy to collect any copies of such medical periodicals as can be spared by colleagues living within say, three miles of Charing Cross and to send them to Hong Kong for distribution. A generous response to this appeal will serve as a token of our profound admiration towards Chinese, Portuguese, and European medical and dental colleagues who sacrificed so much for the sake of humanity and for their allegiance to the British Commonwealth of Nations and our Allies—I am, etc.,

THE WHITE HOUSE, Albany Street
London W.1
P. S. SELWYN-CLARKE
Director of Medical Services Hong Kong

Health Service Forecast

SIR.—We are told in the press that the Minister of Health has nearly completed his Bill and will divulge its contents in the near future. In these circumstances it may be useful to note a very significant leader in the *Tribune* of Jan. 11, a newspaper with which Mr Aneurin Bevan is understood to have been closely associated. The statement opens by expressing confidence that "the Bill will have a swift and easy passage when it is introduced in the House later in the year." It is stated quite categorically "that everyone will subscribe at a flat annual rate and that 'the poorest subscriber will be entitled to specialized medical service, and private rooms in hospitals will be allotted to those who need them'."

illness, if there is one. Indeed, this is happening to-day, so that some of the younger psychiatrists are hardly familiar with psychotherapy, in the proper use of the term, though eager enough in mechanical treatment. That this leads to abuses is obvious. For example, I have seen a man who was badly concussed in a motor accident and who had depression afterwards (partly because he had to pay damages and partly because he had killed a woman and was reprimanded for dangerous driving by the judge); this man was given electrical convulsions for his depression, and when I saw him some months later was more or less demented. Again, I have successfully treated by psychotherapy a mild homosexual who had been depressed because of his condition and was treated fruitlessly by induced convulsions without the psychiatrist even inquiring into his sexual life. I have seen a young obsessional advised to have leucotomy without psychotherapy being tentatively suggested. One could easily multiply examples.

It is essential for anyone who attempts to practise psychiatry to learn the intricacies of psychotherapy and to be familiar as well with the mechanical treatments. No self-respecting psychiatrist should be satisfied with restricting his activities to either psychotherapy or organic treatment. If, for example, Dr. Winnicott rejects treatment other than psychotherapy, how does he treat such illnesses as general paralysis, or does he leave this to others less doctrinaire? In my opinion, unless we as psychiatrists can diagnose and treat *any* mental or nervous condition, whether organic or psychogenic, which may occur in our patients, we shall never win or hold the respect of our colleagues in other specialties.—I am, etc.,

London, W.1.

CLIFFORD ALLEN.

Responsibility for the Anaesthetic

SIR,—At the risk of labouring an old controversy I feel I cannot allow the opinion of Mr. A. Lyall (Jan. 26, p. 144) that "the surgeon rather than the anaesthetist is the person who should decide which anaesthetic should be given" to go unchallenged. This opinion is based on the tacit assumption that whereas the surgeon is a clinician, the anaesthetist is a mere technician—an assumption which is out of date, if it were ever true. That the surgeon should request certain operating conditions is fair enough; it is up to the anaesthetist to provide them so far as is compatible with the safety of the patient; but should the anaesthetist, having assessed the patient clinically, decide that a certain method would be harmful, and wish to employ some other, even if this lacked something of the ideal, the surgeon should abide by his choice.

Whereas in so many cases the surgeon and anaesthetist will obviously agree, and in so many others there will be no definite indications or contraindications for this or that method, there will be the case in which a difference of opinion will arise. When this is so the anaesthetist, particularly the junior anaesthetist, should remember that he will be held responsible for the method of anaesthesia chosen should things go wrong, and is in no way "covered" by the surgeon as would be a student. From these considerations I think it is clear that there is a strong moral and legal obligation binding the anaesthetist: that he should never administer an anaesthetic or employ a method which, on grounds of clinical experience, he considers harmful to a patient—and harmful is a relative word. Even should such an occasion rarely come about, the principle should be clear, and if, after consultation, an impasse should arise, the anaesthetist should remember that his first duty is to his patient.—I am, etc.,

County Hospital, Orpington

BRIAN D. JOHNSON.

Poisoning by *Amanita phalloides*

SIR,—The interesting article by Drs. J. Dubash and D. Teare on "mushroom" (*Amanita phalloides*) poisoning (Jan. 12, p. 45) reminds me of three cases I saw about three years ago, and as the authors remark how few cases have been reported they might be worth recording.

The first sufferer was not my patient, and I unfortunately have no notes on her, but I remember that the outstanding features were jaundice and hallucinations and that she was about 25. While in her hallucinated state she made rather a good remark. It was bedtime in the ward, and when the nurse approached with her vessel she sat up, smiled, and said: "Good, just what I feel like,

and I'd like two lumps in mine." She made a good recovery within a few weeks.

The other two were a mother and daughter, the only two out of five people at the same meal to have eaten mushrooms, and the only two to fall ill. The fungi had been picked in a field near Ipswich. They were ingested on a Saturday morning, and by evening the mother had started to vomit. This continued all night, and on Sunday morning a violent diarrhoea began, with colicky abdominal pains and severe cramps in legs, feet, and hands. By Monday, when she was admitted to hospital, she had improved. A few days later she was constipated and had marked anorexia. She then had considerable tenderness beneath the right costal margin but no other physical signs, until she developed a typical erythema multiforme on trunk, arms, and legs eight days after eating the fungi, which cleared within three days. Her recovery was the uneventful.

The little girl, aged 5, had eaten only a piece of one fungus, and was not taken ill till the Sunday morning, when she was suddenly seized with severe diarrhoea and vomiting. By Monday she was delirious, and in hospital was noted as thin but not notably dehydrated, "parchmenty" in colour and texture of skin, and completely comatose. She was shocked and pulseless, but not cyanosed or jaundiced. Her respirations became more and more rare and gasping and she died that morning. Necropsy revealed a very intense uniform fatty degeneration of the liver.

These last two cases at least illustrate one point—namely, the greater susceptibility of children to the poison, phallin.—I am, etc.,

Milton, Berks.

W. P. U. JACKSON.

Nicotinic Acid Amide in Diabetes

SIR,—Ever since my student days diabetes mellitus has fascinated and intrigued me. At that time I evolved a theory that this only too rampant disease was a deficiency one, the deficiency existing in some vitamin, known or unknown. It was my contention that the islets of Langerhans required an adequate quantity of some special vitamin in order to function normally and that a lack or inadequate quantity would result in islet of Langerhans insufficiency. In order to pursue this question I required an intelligent and co-operative diabetic who was not partaking of insulin therapy. This last essential was necessary in order that the results could not be attributable to the insulin intake. To be brief, massive doses of different vitamins were tried (but not D, E, or K), without any improvement in the blood sugar manifesting itself. One massive dose of nicotinic acid discouraged further investigation "up that alley" by virtue of the almost unbelievably violent recurrent flushing of the entire body. However, I resorted to the nicotinic acid amide instead, and it is the result of this "experiment" that I wish to report.

The patient, a highly intelligent and co-operative man of about 40 years of age, is a foreman in a garage and agreed to try the administration of the amide.

1. On a rigid diet of about 1,200 calories (of which approximately 70 g. was protein, carbohydrate 90 g., and fat about 60 g.) the "fasting" blood sugar was 160 mg. per 100 c.c.m. of blood. In the normal the blood sugar drops below fasting level in two hours. I endeavoured to take the blood from the patient about 2½ hours after the same meal, thus having the blood at the most suitable time.

2. After the administration of 1,200 mg. of nicotinic acid amide in the form of six tablets each containing 200 mg., for a month, the blood sugar registered 60 mg. of sugar per 100 c.c.m. of blood—i.e., a drop of about 100 mg.: a tremendous fall.

3. The patient was then instructed to "eat a normal diet" but to proceed with the administration of his amide. However, becoming rather worried over his "low sugar," he of his own accord reduced the tablets to 400 mg. daily. After about 14 days his blood sugar was again estimated, and registered 120 mg. of sugar per 100 c.c.m. of blood—an increase of 60 mg. over the previous result but 40 mg. below his blood sugar when he maintained a rigid diet but without any tablets, and he was now enjoying "normal" meals.

4. I thereupon instructed the patient to proceed with the "normal" diet, but to increase the dosage of the nicotinic acid amide to the original 1,200 mg. daily. The subsequent blood-sugar estimation registered 100 mg. per 100 c.c.m. of blood. (The normal blood sugar is 80 to 120 mg.)

I have not investigated the patient as fully as I would have liked because of lack of facilities and time, neither have I pursued the investigation in a great number of cases, but the results appear, so far, vastly encouraging. The nicotinic acid amide may be what we have been looking for.—I am, etc.,

"Cord Round the Neck"

SIR.—In the course of attendance on about 5000 confinements I have never seen a stillbirth which I could ascribe to the above cause. I think it is a possible cause in the absence of a medical man or a trained midwife, but not otherwise. On one occasion I feared the child would be strangled so I cut the cord at once. The cord was twice round the neck and taut from the navel to the neck and from the neck to the placenta. The child had been shot out suddenly, so that there was an extra pull on the cord. I was unable to get my fingers underneath it. I am inclined to agree with Mr Mortimer Reddington (Jan 19, p. 109) that such a diagnosis should be regarded with grave obstetric doubt—I am, etc.,

FRIDAY

ROBERT ANDERSON

Medical Future of the Colonies

SIR.—I have just received the *Journal* of Nov. 17, 1945, and in view of the Commission on Salaries inquiry in the West African Colonies appointed by the Secretary of State for the Colonies to start early in Jan., 1946, I read with great interest the leading article on the medical future of the Colonies (p. 693). On reaching the first sentence of the concluding paragraph I received a shock. "These reforms are suggested only for the European medical officers." This at once raises the racial question with its unscientific invidious treatment meted out to the non-Europeans in the services of the different British colonies. Does the B.M.A. support this distinction based on "colour"? Does the B.M.A. hold no brief for its non-European members who are employed by the British Colonial Governments?

I may claim to some extent to be representative of the non-European medical officers in the Colonies in general and of Sierra Leone (West Africa) in particular, having just retired after 32½ years' service in the Sierra Leone Medical Service as distinct from the Colonial Medical Service. I have been a member of the B.M.A. since 1912. Why should this editorial deal with the grievances of only one part of its members pointedly? Non-Europeans equally with their European colleagues are entitled to all the facilities of the Association and to the help of the B.M.A. in the alleviation of their legitimate service grievances.

Can it be, then, that the writer seriously considers that we have no grievances or that they are too trivial to be considered? Very early in the article it is stated: "It is no exaggeration to say that before this war most people were profoundly ignorant of conditions in this Empire." This persistent overlooking and ignorance of the non-European civil servants in the Colonies is one of them.

The purport of the rest of this letter is to show very briefly the invidious distinctions and inequalities of conditions of service between European and non-European medical officers in one Colony—Sierra Leone—since the formation of the West African Medical Service by Chamberlain in 1902. Prior to this since 1865 African medical officers had been continuously in Sierra Leone, frequently in those early days half or two-thirds of the medical staff were African, receiving the same pay and promotion as their European colleagues. In the 'seventies one was head of the medical department of the Gambia with a junior European under him and in the 'nineties a similar state existed on the Gold Coast. The Africans had all been trained in the medical schools in the U.K. and passed the same (frequently higher) examinations and been registered in exactly the same way as their European colleagues.

With the formation of the W.A.M.S. the colour bar was introduced and no West African could enter the West African Medical Service. Thus there were two services side by side—the W.A.M.S. (European) and the local Colony service (African). In 1943 the W.A.M.S. was absorbed into the larger Colonial Medical Service, and though in the more recent advertisements for recruits in the medical press and the official regulations no mention is made of it the colour bar still exists, as so far no non-European has been appointed to West Africa and African applicants have been offered posts in the local Colony services. Thus there are still two services. So, regardless of what policy may in the future be adopted towards the training of medical men from the indigenous peoples, there is at present a definite body of non-European personnel in the

West African Colonies (three hold specialist posts and areas have been awarded the M.B.E.), and they cannot be passed over so easily. Not only were these non-European medical officers on a much smaller salary scale, but until quite recently there was no promotion for them from the grade of medical officer and though qualified they were not employed on the health side. In addition their European colleagues have the following privileges all of which have a definite colour line: longer vacation leave and local leave with salaries paid on the same good furnished quarters, or an allowance in lieu of conservancy when in Freetown the capital, free accommodation, water supply, and exemption from municipal rates, per diem on a higher scale and if re-employed when on per diem receive an additional 15% and then still have a much longer period of full pay before coming on to half pay.

I have had interviews and correspondence with several of the medical and Dominion secretaries of the B.M.A. since 1922 and have applied for the help of the B.M.A. to redress some of the above inequalities. The above facts are on the file in the B.M.A. office—and in spite of this we non-Europeans are passed over so easily—I am, etc.,

M. C. F. EASON
Sierra Leone Medical Officer (General Practice)

FRIDAY

Medical Journals for Hong Kong

SIR.—Would you allow me the hospitality of your columns to make an appeal on behalf of my colleagues in Hong Kong? Below is an extract from a letter just received from one of the Chinese doctors who remained at his post throughout the 3½ years of Japanese occupation, at my earnest request in order to provide medical and health services for the prisoners of war and civilian internees, their unattended wives, children and dependants, and for the general community. Such men remained loyal to the Allied cause despite every effort by the Japanese military and civilian authorities to win them over with alluring promises of advancement. Hardship, torture, starvation and even imprisonment and all that went with it including mistreatment and loss of health and honour, failed to break their spirit and they courageously carried on their duty even after my removal by the Kempeitai from the island. I quote from one of several similar letters received from the Far East:

"The doctors here are terribly short of medical literature. I would be useful to collect some back numbers of the *Lancet*, *British Medical Journal*, *Practitioner*, *British Journal of Surgery*, etc., that are wanted by our British professional brothers, to be circulated among doctors of the various hospitals. No doubt all of us here in Hong Kong want to know what has happened in the past few years. Honestly we are not jealous at the aid and doctoring and wealth brought back by friends who went away from Hong Kong during the Japanese occupation, but we do want to catch up intellectually with what we missed."

On the receipt of a postcard I shall be very happy to collect any copies of such medical periodicals as can be spared by colleagues living within say, three miles of Charing Cross and to send them to Hong Kong for distribution. A generous response to this appeal will serve as a token of our profound admiration towards Chinese, Portuguese, and Eurasian medical and dental colleagues who sacrificed so much for the sake of humanity and for their allegiance to the British Commonwealth of Nations and our Allies—I am, etc.,

THE WHITE HOUSE, Albany Street
London, W.1
P. S. SELWYN-CLARKE
Director of Medical Services Hong Kong

Health Service Forecast

SIR.—We are told in the press that the Minister of Health has nearly completed his Bill and will divulge its contents in the near future. In these circumstances it may be useful to note a very significant leader in the *Tribune* of Jan. 11, a newspaper with which Mr Aneurin Bevan is understood to have been closely associated. The statement opens by expressing confidence that "the Bill will have a swift and easy passage when it is introduced in the House later in the year." It is stated quite categorically "that everyone will subscribe at a flat annual rate and that 'the poorest subscriber will be entitled to specialized medical service, and private rooms in hospitals will be allotted to those who need them'."

The policy which the Minister has announced with regard to the purchase of practices finds its explanation in the following paragraph: "Apart from areas deemed to be fully served by doctors, the medical practitioner will be free to set up practice anywhere; private practices may continue so long as they are in public demand, but, as they fall vacant, they will be filled in conformity with the district's special needs instead of being offered to the highest bidder."

The free choice of doctor which is dealt with in the B.M.A.'s Principle III is explained (and limited!) in the following paragraph: "There will be no interference with the right of the patient to choose his own doctor and there will be nothing to stop him from paying a private fee, *in addition to his annual subscription* (the italics are mine), if he can find no better use for his money." We have been warned.—I am, etc.,

House of Commons.

E. GRAHAM-LITTLE.

Questionnaires, Past and Future

SIR,—May I suggest that one question, such as the following, is all that is necessary: "Do you wish to enter a centrally controlled service?" If the service be centrally controlled the central authority could convert, by regulation and without reference to Parliament, an originally attractive service into one which would be repugnant to both patient and doctor. If the present system, which in the main is on a basis of peripheral control by patients and doctors, were set free from unnecessary financial restrictions nothing would stand in the way of the rapid adaptation of its structure to meet the various and varying demands made upon it to the advantage of all concerned (except those whose pleasure is to exercise power over the lives of their fellows). A similar question to the one suggested above was recently put to 30,000 doctors. Of the 10,000 who made the effort to reply, 77% were opposed to a centrally controlled service. * Full details of this questionnaire are, I believe, available for the use of the Negotiating Committee.

As part of a comprehensive and long-term policy directed against the freedom of the individual all official proposals, actual and foreshadowed, conform consistently to a centrally controlled type of organization. In this the executive of the B.M.A. acquiesces. The Negotiating Committee avoids the fundamental issue and discusses mere details.—I am, etc.,

Bexley, Kent.

E. U. MACWILLIAM.

A Burning Topic

SIR,—At a time when the future of the medical profession in this country and the immediate prospects of so many of its members are in the balance, it can only cause irritation among your readers if you continue to give up columns of space to letters, however flippant or however magisterial, advocating that a venereologist should be called a venereologist (or alternatively a "moskovend" or a "priapologist") or that the operation of myringotomy should be called "syringomyringodiacentesis." There are more burning topics. For example, the present plight of those many practitioners who through war service, voluntary or otherwise, have lost their practices, and on demobilization find that they are debarred from acquiring new ones, so that they can now only go to work as salaried employees in other men's practices.

There is a feeling in the air that in future general practitioners will be paid, not according to how good they are at general practice, but according to the letters after their names. The natural course, then, for those now suspended in this limbo, especially for those with definite specialist ambitions (which they may have forgone for the security of the practices they have now lost), would be to use the Government scheme for rehabilitation, by a Class I or a Class III appointment, to acquire some higher or specialist qualification. This, it seems, is completely ruled out under the scheme. Neither the man who has spent any time in general practice nor the specialist is allowed anything beyond a contemptible two-week refresher course. If one pays a visit to the H.Q. of this postgraduate scheme one may be confronted by an individual who at the mention of the word "right" or "claim" jumps up from his chair, flourishes a disability at one, and declares that he has no claim against the country; and while one is still gasping from the impact of such mawkishness the interview comes to an end.

One is led to understand that the only people to benefit by this scheme are those who have avoided war service or served in the E.M.S. long enough to become graded specialists. Was this the country's intention in setting aside this sum for rehabilitation of Service doctors? Have we (who have lost most and need most rehabilitation), in fact, no claim on these facilities nor right to ask for them? Can we not now use these opportunities, which we had so counted on during long evening hours of study in the Forces?

I suggest that we hear no more of "moskovends" or of "syringomyringodiacentesis," and that the space thus released be given over to one weekly letter on this subject until enough interest has been aroused to get something done.—I am, etc.,

Tacolneston Norfolk.

W. J. GARDNER.

A Tribute to Honorary Staffs

SIR,—Undergoing rehabilitation at my old London teaching hospital I have been forcibly struck by the very apparent ageing and tiredness of those of the honorary staff who remained behind to carry on during the war years. This change is apparent enough when I recall their pre-war appearances, and it becomes even more obvious when I compare them with their youthful-looking colleagues now returned from the Services. An acid tongue might remark that everyone knows how little work was done in the Services, but in the case of Service specialists I am quite certain that most have done their full share. The difference is due to the drag of everyday wartime civilian life, the frustration of shortage of nurses, of laboratory staff, of instruments, etc., the drag of travelling, and, not least, the very considerable amount of time spent by many under constant threat of enemy air activity.

Not only do I wish to pay a belated tribute to their devotion and loyalty, but I want to point out that the teaching hospitals are now faced with having tired men both to teach the new generation and to help deal with the very difficult years stretching before the medical profession. My humble suggestion is that during the next few years these leaders of our profession should be rehabilitated by six months in Canada and the U.S.A., studying their own specialty and incidentally resting, feeding, and rejuvenating.

Feeling that the motives behind a letter of this nature might be misunderstood, I would prefer to remain

"EX-MAJOR, R.A.M.C." (Non-specialist).

A United Nations Medical Association

SIR,—Now that the United Nations Organization is meeting in London, is it not apposite to consider the possibility of forming a United Nations Medical Association? The excellent achievements of the League of Nations Health Organization are known and appreciated (though not perhaps as widely as they should be). Undoubtedly this or a similar body must continue to study and organize public health projects of international importance. But some of us working with U.N.R.R.A. recognize the need for an organization somewhat similar to the B.M.A. or the A.M.A. The social and professional benefits which such an organization could offer to our numerous displaced and distressed colleagues in many countries are apparent to all who have worked in the camps. These, our colleagues, have now no homeland, no books or journals (though we try to make good this deficiency). The aid which might come to them through U.N.M.A. should be socially and psychologically preferable to selective charity from any other source. It would enable them to identify themselves with their professional fellows in every land.

The above is, of course, but an expedient reason for proposing the function of such a body as U.N.M.A. at the present time. Other important professional reasons will be obvious. Furthermore, it is reasonable to suppose that so large an international body of mainly cultured, tolerant, and enlightened people would form a considerable contribution towards maintaining world peace. The first step that suggests itself in the development of such an organization is the publication of a U.N.M.A. journal to be printed in English and several other languages. The choice and decision as to these languages should not lead to as much dispute as some might anticipate. It requires no fertile mind to imagine the interest and value such a pioneer journal should otherwise possess.—I am, etc.,

U.N.R.R.A., Austria.

F. M. PURCELL.

Obituary

SIR COMYNS BERKELEY, M.D., M.Ch.

F.R.C.P., F.R.C.S., F.R.C.O.G., M.M.S.A.

The death on Jan. 27 of Sir Comyns Berkeley, which we announced last week with great regret, removes one who had been for the best part of half a century in the front rank of obstetric and gynaecological surgeons in this country. He was a leading figure of the Middlesex Hospital, which he entered as a student in 1888, just ten years after his friend and mentor, Sir John Bland-Sutton, had entered it. Comyns Berkeley had the bearing of a physician of a more sumptuous age—one could imagine him attending at St. James's Palace for the delivery of Queen Anne, though with him in charge her maternal record would have been much less disappointing—but no man was more alive to practical issues or did more to raise the standard of midwifery in this country.

George Harold Arthur Comyns Berkeley was born in Chelsea on Oct. 16, 1865. At the age of 13 he went to Marlborough, and at 18 to Cambridge (Caius), where he remained for five years, taking the B.A. (Natural Sciences Tripos) in 1887. Then came his years at Middlesex, and he qualified M.B., B.Ch. in 1892. Though he worked for a time as house-physician at the Brompton Hospital and at the Hospital for Sick Children, Great Ormond Street, the bent of his career quite early was towards obstetrics, and he served his own hospital, Middlesex, as obstetric house-surgeon, obstetric registrar, and tutor in obstetrics and diseases of women. In 1903 he was elected to the visiting staff of the Middlesex, and his association with that hospital, and

[C. Vandysk, Ltd.]

his deep affection for it, continued until the end of his life. He was also consulting surgeon to the City of London Maternity Hospital and to the Chelsea Hospital for Women, and consulting gynaecological surgeon to the Hornsey, Eltham, and Clacton Hospitals, and to the London County Council Radium Centre at Lambeth. During the war of 1914-18 he was surgeon-in-charge of the Clacton Military Hospital, Eastern Command.

No man exercised a larger influence on the standard of midwifery in this country. He was at one time or another examiner in midwifery and diseases of women to every university in England and Wales except two, to two of the Scottish universities, to the English Conjoint Board, and to the Society of Apothecaries. His long-continued work for the Central Midwives Board included the role of examiner, member of the Board, and eventually for ten years its chairman. Under him the Board tightened up its regulations, insisted on the observance of them in the letter as well as in the spirit, and greatly raised the status of midwives by the enforcement of an examination system and discipline which, hardly as it might bear upon women who had drifted into midwifery without adequate training or preparation, was no more than the importance of their work demanded. He also endeavoured to secure that medical students as well as pupil-midwives should have a sufficient number of cases. He did much to establish pre-maternity supervision—really a quite modern practice. He was interested also in general nursing, and the Royal College of Nursing for many years had the benefit of his presence as honorary treasurer and friend.

In his surgical practice he was a most careful operator, insistent upon every antiseptic and aseptic precaution, and on the fastidious preparation of the patient. He was exceptionally fortunate in having during his years of operative work at the Middlesex the same anaesthetist, his friend Dr. Herbert Charles. Berkeley was not afraid of speaking his mind on any subject or of expressing dissent from new departures in obstetric practice

which seemed to him unwise or precipitate. At the Portsmouth Meeting of the British Medical Association in 1923 he delivered an address on the use and abuse of the obstetric forceps, and afterwards, he said, received considerable abuse, with the result that his banking account suffered for a time. He had his own views as to the reason for the stubborn figure of maternal mortality a few years ago. He thought it was due to lack of antenatal care, either the neglect of the local authorities to make provision or the unwillingness of women to avail themselves of it. Ignorance, carelessness, undue haste were to him the three malignant spirits which attended childbirth. His services were secured by Sir George Newman, then Chief Medical Officer of the Ministry of Health, to advise medical officers of the Ministry in an investigation into maternal mortality. The reports of that investigation pay high tribute to his services. Radium treatment in gynaecological conditions interested him, and he was a member of the National Radium Committee and vice-chairman of the National Radium Trust. He first used radium in carcinoma of the cervix in 1912, but took a conservative attitude.

Comyns Berkeley joined the British Medical Association in the early 'nineties. In 1925 he was elected president of the Metropolitan Counties Branch, when his presidential address bore the title "Save the Women and Children." In the following year he was president of the Section of Obstetrics and Gynaecology at the Nottingham Meeting. Though he took no particular part in medico-political affairs, he was a most loyal member of the Association and a diligent reader of its *Journal*. Even when he was away on long visits abroad he insisted on copies of the *B.M.J.* being saved for him and carefully studied them on his return. He was himself an editor; under his direction for over twenty years the *Journal of Obstetrics and Gynaecology of the British Empire* became one of the leading special journals. He was a most prolific writer, being the author of many books and treatises which passed into a number of editions. These include a *Handbook for Obstetric Doctors and Midwives*, of which a twelfth edition appeared in 1943; *Gynaecology for Nurses*, which is still in great request; and an *Atlas of Midwifery*. The title of this last work was changed in later editions to *Pictorial Midwifery*; it contains some 250 pictures illustrating practically all the points in connexion with the teaching of midwifery which lend themselves to pictorial representation. He edited the two popular textbooks known as *Midwifery by Ten Teachers* and *Diseases of Women by Ten Teachers* each of which has reached a seventh edition. With his junior colleague Victor Bonney he wrote the well-known and deservedly praised *Textbook of Gynaecological Surgery*, now in its fourth edition; also *Difficulties and Emergencies of Obstetric Practice* (third edition, 1920) and *Guide to Gynaecology in General Practice*.

Sir Comyns Berkeley, who was knighted in 1934, was a Fellow of all three Royal Colleges—Physicians, Surgeons, and Obstetricians and Gynaecologists, and of the last-named he was for long a member of Council and its first treasurer. He was also Honorary Master of Midwifery of the Society of Apothecaries. Just before the war he was nominated an honorary member of the German Society for Gynaecology. Socially he was a man much sought after, a popular member of the Garrick and other clubs, a keen golfer and rider to hounds, and an admirable host. But his life was largely absorbed by his profession, which he pursued with undeviating energy and zest until well beyond the age of normal retirement. In recent years his health seemed precarious, and the death of Lady Berkeley during the war was a heavy blow.

Mr. VICTOR BONNEY writes:

As Comyns Berkeley's oldest surviving friend and colleague I want to add something personal to the obituary notice. My recollection of him goes back to 1891 when he was house-surgeon to Mr. Henry Morris and I a young student, but we did not come into near contact till 1898, when I went to Chelsea Hospital for Women as resident surgical officer, he then being the junior assistant surgeon. From that time forwards our association was very close, and for many years we worked as a team of two.

At the end of the last century most of the gynaecologists were not fully trained surgeons, but physicians on whom a degree of surgical proficiency had been grafted, but we had the advantage of a close association with Bland-Sutton, and both of us owe a great deal to him. We endeavoured to advance gynaecological surgery and took up Wertheim's operation (then newly invented) with enthusiasm.

In all our early cases of this operation we assisted one another, and at intervals thereafter published the results we had obtained.

The idea of writing a textbook on gynaecological surgery took shape in 1905, but the question of illustrations held it up as neither of us could afford the heavy expense of a professional artist. I therefore had to teach myself to draw, and the process was a long one. The text was written conjointly between 9 p.m. and 2 a.m., and to keep us awake we consumed a bottle of old port at each sitting. The book appeared in 1911. Thereafter we collaborated in four other books, the last (in conjunction with Douglas Macleod) not long before the last war.

From 1914 to 1918 we were the surgeons to the military branch of the Middlesex Hospital at Clacton-on-Sea. It was a first-line base hospital and over 10,000 wounded soldiers passed through our hands. It was necessary to carry on the teaching and surgical work at Middlesex and Chelsea Hospitals, so we arranged that each of us should spend half the week in London and half at Clacton. The half in London, when each of us did his own work and that of his colleague, was very strenuous.

The record of his life's work, even in epitome, is an amazing one, and it might be thought that the spending of so much energy on intensive labour would leave little room for the graces and pleasures of existence. But not at all; he possessed a native humour, a geniality, a toleration, and a kindness of heart which made him an ideal companion, and at any social gathering, private or public, where fun and good fellowship were called for he was a priceless asset. A *bon viveur* by nature and inheritance, joying in good company, especially when it was intimate and gossipy, and possessing an intense relish for the pleasant things of life, he held with the poet that "laughter and the love of friends" were of all things the most worth winning. I with many other of his host of friends will remember with affectionate regret the dinners, perfect in substance and service, that he used to give at his own house or at the Garrick, nor less those jovial suppers of perfect Stilton and audit ale which, at 2 a.m., succeeded several hours spent in hard literary work.

In the last few years of his life domestic misfortune beset him; his house in Wimpole Street was badly damaged by a bomb, as likewise was the house he removed to and the office wherein he worked; and presently his health began to fail, and the death of his dearly loved wife was the final blow. Nevertheless, with indomitable resolution he continued editing his journal and presiding over his Board, and undismayed carried on to the end.

In paying this tribute to the life's work of a very old and loved colleague and friend I cannot but think it teaches these two great lessons: first what enormous capability there is in unfaltering persistence—in 50 years I never saw Berkeley lounge or be idle, he was always doing something; and secondly that time is much more spacious than most of us think, there being within it, if fully utilized, ample room for both great work and great play.

W. E. THOMAS, M.D., J.P.

Prof. GILBERT I. STRACHAN sends the following appreciation:

William Evans Thomas, who died at Porthcawl on Jan. 20 in his 83rd year, was a native of Bala in North Wales. Soon after graduation at Edinburgh he settled in practice in the Rhondda Valley, where, at Ystrad Rhondda, he practised for almost sixty years. He was a keen clinician and kept well abreast of modern advances in his profession, so that his practice became one of the largest in the Rhondda Valley. In spite of this he found opportunity to take a leading part in public affairs, and much of his time and energy in this respect was devoted to the interests of the British Medical Association. He was at different periods honorary secretary and chairman of the North Glamorgan and Brecknock Division, twice president of the South Wales and Monmouthshire Branch, chairman of the Welsh Committee, and vice-chairman of the Welsh Contract Practice Committee. He was also a member of the Representative Body and for a number of years a member of Council. He was one of the original members of the Rhondda Urban District Council, also a member of the governing bodies of the Welsh National Tuberculosis Association, of the National Museum of Wales, of the University College of South Wales and Monmouthshire, and of the Welsh National School of Medicine, as well as of the Board of Management of Cardiff Royal Infirmary. Twenty-five years ago he was appointed a Justice of the Peace.

This sketch far from exhausts the many activities of this remarkable man, who in private life was one of the most cheerful of companions, with an impish sense of humour and a perfect "leg-puller," while he was an ideal host. "W. E.," as he was always known, had the keen-witted enthusiasm of his race; he was always angered at any example of injustice and was ready to fight at any time in the interests of the under-dog. A Welsh-speaking Welshman, he was intensely proud of his country, its achievements, its art, its culture, and its language; and as the best type of Welsh patriot he could always be relied on to maintain the interests of gallant little Wales. His busy life left him but little time for recrea-

tion or sport, and he had small inclination in this direction; work was his mainstay, and many a summer "holiday" was spent at a B.M.A. Annual Meeting.

The death of "W. E." represents the snapping of still another of the few links that connect us with that generation of medical men, the old school, who almost grew up with the Welsh coalfields. They were a hardy and conscientious body of men, and their earlier days on foot or on horseback in all weathers were in marked contrast with the comfort of the latter-day motor-car. Dr. Thomas had the knack of appealing to younger men, with whom he kept constantly in touch, so that his range of acquaintance was enormous; in this way his passing creates a wide gap which it will be difficult to fill, and his absence will be felt by a wide circle far beyond his own generation. At the funeral at Glyn Taff Cemetery, Pontypridd, representatives of many public bodies, including the Welsh National School of Medicine, were present to pay their last respects. It was well said of him that few men had touched life at so many points as he had.

ALFRED EDDOWES, M.D., M.R.C.P.

Dr. Alfred Eddowes, who died on Jan. 15 at Woodford Green at the age of 95, joined the British Medical Association as long ago as 1875, and held office in the Section of Dermatology at three Annual Meetings—as secretary in 1901 at Cheltenham, as vice-president in 1910 in London, and as president in 1914 in Aberdeen.

The son of a medical man, he was born at Pontesbury, Salop, and from Shrewsbury School went to the University of Edinburgh, where he won a medal in physiology and graduated M.B., C.M. in 1873, taking the M.D. three years later. After postgraduate study in London at St. Bartholomew's Hospital, and in Vienna, Hamburg, and Paris, Eddowes was resident medical officer at the Royal Salop Hospital for over four years, and then worked in general practice in his native county for eleven years. Coming to London he specialized in dermatology, took the M.R.C.P. in 1897, and became physician for skin cases at the West End Hospital for Nervous Diseases, and also physician to the skin department of St. George's and St. James's Dispensary and to the St. John's Hospital for Diseases of the Skin in Leicester Square. Later he joined the staff of the Western Skin Hospital and was honorary dermatologist to the Artistes' Section of the Stage Guild. He was elected a corresponding member of the French Society of Dermatology and of the Italian Society of Dermatology and Syphilology.

Universities and Colleges

UNIVERSITY OF OXFORD

In a Congregation held on Jan. 24 the following medical degrees were conferred:

D.M.—
B.M.,
A. J. Os, ... S. P. Rawlins, C. G. White, I. C. Todd
(in absence).

UNIVERSITY OF CAMBRIDGE

The Trustees of the Nuffield Foundation have offered to the University financial support for an investigation (under Prof. F. C. Bartlett at the Psychological Laboratory) on causes and results of ageing, dealing with characteristics and changes of human function which are associated with different age groups, with particular reference to adult groups. The grants that the Trustees have in mind are a non-recurrent one of £2,000 for initial capital outlay, and a recurrent grant of £6,000 a year for three years in the first instance, with the possibility of renewal for a period not exceeding three years, making six years in all. Should the whole of the grant not be expended in any year, the unexpended balance should be carried forward for use later in the grant period.

The Cambridge University Reporter for Jan. 29 contains a report by the Council of the Senate on the establishment of a professorship of radiotherapeutics, and a report by the General Board on the constitution of a department of radiotherapeutics. The Faculty Board of Medicine has recommended unanimously that a professorship in this subject should be established for Dr. J. S. Mitchell, who was medical officer in charge of the radiotherapeutic centre at Addenbrooke's Hospital until he went to Canada on Government service in 1944. This recommendation is approved by the Council, who further recommends that the chair should be limited to one term and primarily assigned to the Faculty of Medicine, and that the professor shall not engage in private practice. The General Board

recommends that a department of radiotherapeutics be constituted and placed in the Faculty of Medicine, and that the head of this department be the professor of radiotherapeutics. If the University approves the proposed constitution Dr Mitchell will work partly in Addenbrooke's Hospital, in the post from which he had leave of absence, and partly in a university department to be equipped and maintained by the University. What the General Board now proposes is the second step in the development of a school of clinical research and postgraduate teaching along the lines described in an earlier report on the constitution of a department of experimental medicine. The opportunity to constitute a department of experimental medicine arose from the offer of the Medical Research Council to provide the whole stipend of Dr R. A. McCance as professor of experimental medicine, whose department was set up in May, 1945.

On the nomination of the Faculty Board of Medicine Prof. R. A. McCance has been appointed asessor to the Lucas Professor of Physics for the year 1946.

At a Congregation held on Jan. 25 the following medical degrees were conferred by proxy except on those whose names are marked with an asterisk:

MD—J. F. Paterson
MB, BChir.—R. C. Allison, D. J. Anson, J. C. Baylis, W. Backley, E. W. Deane, A. McK. Elliott, A. E. Platt, A. L. Leitch, J. Glazer, D. Hamilton, J. Jordan, P. B. Kunkler, P. A. Merron, P. D. W. H. G. Peck, B. R. Pollard, J. W. T. Redfern, J. T. Rossiter, C. C. D. Sturt, E. B. G. Smith, R. H. Thompson, P. Watten, R. H. Winkler, C. J. Wilkin

UNIVERSITY OF LONDON

The headquarters staff of the University at Richmond College has now returned to the Senate House in Bloomsbury (tel. Museum 8000). The department of the superintendent of examinations and the publications department will remain at South Kensington until further notice.

Mr. John B. Hunter, M.Ch., F.R.C.S., has been appointed as a representative of the Faculty of Medicine on the Senate for the remainder of the period 1942-6, in place of the late Sir Girdling Ball. Mr. Hunter is succeeded by Dr. H. E. A. Boldero, F.R.C.P., as representative of the General Medical Schools on the Senate for the same period.

Under the present regulations, applications for grants in aid of research are invited annually and are to be received at the University by March 31 in each year. It has now been decided that more frequent allocation is desirable, and the revised dates of application for grants from the Central Research Fund, the Dixon Fund, and the Thomas Smythe Hughes Medical Research Fund will now be March 31, July 31, and Nov. 30 in each year.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following candidates were successful at the recent Primary Fellowship examination conducted by the College:

J. A. Alexander, M. Burdman, E. F. Chin, Daphne W. Chun, N. A. Cust, E. O. Dixon, A. N. B. Fitzhardinge, I. G. Graber, D. P. Greaves, F. J. Hedden, A. M. Khan, T. L. T. Lewis, R. J. Manekshaw, R. Nigam, N. K. Parikh, W. H. Power, D. B. Robertson, D. P. Robertson, G. P. A. Sechurn, Homa V. G. M. Shaibany, D. H. Thompson, B. H. Wadiaz, R. W. E. Watts.

SOCIETY OF APOTHECARIES OF LONDON

Lord Moran, P.R.C.P., will deliver a lecture entitled "Into Battle" at Apothecaries' Hall, Black Friars Lane, Queen Victoria Street, E.C., on Tuesday, March 12, at 8 p.m. Members of the medical profession and senior students are cordially invited to attend.

The Services

The following have been mentioned in dispatches in recognition of gallant and distinguished services in the field: Major (Temp.) R. Mackay, M.C., Capt. A. H. Weston and J. E. Wooding, R.A.M.C., and Capt. P. R. Das-Gupta, I.M.S.

The Efficiency Decoration has been conferred upon the following officers of the Territorial Army: Lieut.-Col. (Temp. Col.) C. R. Croft, Majors (Temp. Lieut.-Cols.) P. R. Mitchell, O.B.E., and H. G. Wimbush, and Capt. (Temp. Major) G. S. Adams and G. T. Pitts, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Previously reported missing, now reported to have died on Feb. 15, 1942, in Japanese hands—Squad. Ldr. Eustatius William Barton Griffiths, R.A.F. Reserve.

Died while a prisoner of war in Japanese hands—Fl. Lieut. Raymond George Blackledge, R.A.F.V.R.

Died—Fl. Lieut. James Lawrence Connor, R.A.F.V.R.

Died of wounds in India—Lieut. Austin Stuart Carruthers, R.A.M.C.

Killed on Active Service with C.M.F., May, 1945—Capt. Cecil Willoughby Richards, R.A.M.C.

Medical Notes in Parliament

Pneumoconiosis Investigations

Mr. PETER FREEMAN suggested on Jan. 22 that the Minister of Fuel and Power should have a special inquiry made into the question of stone-dusting and coal-dust problems in connexion with coal-cutting and conveying machines underground, with reference to the effects of both kinds of dust upon miners' lungs, and as contributory causes of lung diseases. Mr. SHINWELL said measures to reduce dust in coal mines were already the subject of investigation and action by the industry and by the Inspectors of Mines. Though he was satisfied that much progress was being made, particularly in South Wales, this would have to be accelerated. In addition a joint committee, composed of representatives of his Department and the Medical Research Council, was securing a research unit in South Wales dealing with the cause, treatment, and prevention of pneumoconiosis. There had been an increase in the incidence of lung diseases among miners, but this was not attributable to stone dust.

Research in Atomic Energy

Mr. ATTLEE announced on Jan. 29 that Lord Portal of Hungerford had been appointed as head of an organization for production of fissile material for use in research into and experiments with atomic energy. Prof. J. D. Cockcroft had been selected for the post of director of the atomic research station at Harwell, near Didcot. On Jan. 31 Mr. Attlee added that the Government intended research and production should be carried on in this country on a scale sufficient for the development of atomic energy in co-operation with other nations. He could not estimate when any stated rate of output of the material would be achieved.

Discussions by the Minister of Health

On Jan. 31 Sir HENRY MORRIS-JONES asked Mr. Bevan why, in his recent interview with some representatives of local authorities concerning his proposals for hospital administration in his forthcoming National Health Bill, they were forbidden by him to consult their associations or to divulge his proposals. Mr. BEVAN replied that the Government's proposals for a National Health Service would be published in the proper manner by the submission of a Bill to Parliament. Before settling final details of that Bill he was seeking advice on various points from expert representatives from local government and other fields. He did not ask them to commit the local authorities or other bodies to any particular proposal. His discussions with them must obviously be confidential.

Medical News

The following radiological meetings are announced: Thursday, Feb. 14, at 8 p.m., at British Institute of Radiology (32, Welbeck Street, W.), Dr. L. G. Blair, "Interpretation of Children's Chest X-rays." Friday, Feb. 15, at 2.30 p.m., at Royal College of Surgeons of England (Lincoln's Inn Fields, W.C.), Diagnostic Section of Faculty of Radiologists, Dr. E. Rohan Williams and Mr. Leonard G. Phillips, "The Value of Antenatal Radiological Pelvimetry," followed by a discussion to be opened by Mr. Aleck W. Bourne. Friday, Feb. 15, at 8 p.m., Radiology Section of Royal Society of Medicine at 1, Wimpole Street, W., discussion on "The Radiotherapy of Brain Tumours."

The Association of Scientific Workers, in co-operation with kindred organizations, has arranged a conference on "Science and the Welfare of Mankind" to be held at the Beaver Hall, Garlick Hill, London, E.C.4, on Friday, Feb. 15, at 7 p.m. (chairman, Sir Robert Robinson, P.R.S.), Feb. 16 at 2.30 p.m. (chairman, Sir Richard Gregory, F.R.S.), and Feb. 17 at 10 a.m. (chairman, Prof. A. V. Hill, F.R.S.) and 2.30 p.m. (chairman, Sir Robert Watson-Watt, F.R.S.). The subjects of the four sessions are science and world needs, implications of recent scientific development, the responsibilities of scientists in modern society, and the organization of science. Inquiries should be sent to the Association of Scientific Workers, 73, High Holborn, W.C.1 (telephone, Chancery 5607).

Dr. Geoffrey Evans will read a paper on "Physical Methods in the Treatment of so-called Psychosomatic States" before the British Association of Physical Medicine at 11, Chandos Street, W., on Wednesday, Feb. 20, at 5.30 p.m.

A meeting of the Clinical Society of the Royal Eye Hospital will be held at the hospital on Wednesday, Feb. 20, at 5.30 p.m., when a talk will be given by Dr. Clifford Hoyle on "Hypertensive and Arteriosclerotic Heart Disease."

The following Chadwick Public Lectures have been arranged: Feb. 19, 2.30 p.m., at Royal Society of Tropical Medicine, 26, Portland Place, W., Dr. A. G. G. Thompson, "Land Utilization in Relation to the Public Health"; March 5, 4.30 p.m., at University of Sheffield, Dr. S. A. Henry, "Medical Service in Industry"; May 7, 2.30 p.m., at Caxton Hall, Westminster, Major Eyre Carter, "The Rehabilitation of Stateless Persons and its Hygienic Bearings"; June 20, 4 p.m., at Chelsea Physic Garden, Swan Walk, S.W., Dr. Ellen Delf, "Plants in the Service of Mankind." Admission to the lectures is free, and further particulars may be had from the secretary of the Chadwick Trust, 204, Abbey House, Westminster, S.W.1.

The Microbiological Panel of the Food Group of the Society of Chemical Industry will meet on Wednesday, Feb. 20, at 6.30 p.m. in the rooms of the Chemical Society, Burlington House, Piccadilly, W.1, when Mr. S. E. Jacobs, Ph.D., will read a paper on some aspects of disinfection. Members may introduce friends in person.

The London Industrial Groups of the Royal Society for the Prevention of Accidents has arranged a one-day conference with a view to encouraging the practical application of the findings of research. It will open at Caxton Hall, Westminster, at 10 a.m. on Monday, Feb. 25. Dr. R. S. F. Schilling will speak on the work of the Industrial Health Research Board, Mr. H. C. Weston on lighting and vision in relation to accidents, Mr. Eric Farmer on the human factor in accidents, and Dr. T. Bedford on heating and ventilation in relation to accidents. The conference fee, including buffet luncheon, tea, and copy of printed proceedings, is 15s. for each delegate, payable to the Royal Society for the Prevention of Accidents; it should be sent to the chairman, London Industrial Co-ordinating Committee, 52, Grosvenor Gardens, S.W.1.

A series of lectures will be given at the Royal Institute of Public Health and Hygiene (28, Portland Place, W.) on Wednesdays, at 3.30 p.m., from Feb. 27 to April 10, both dates inclusive. Details will be published in the diary column of the *Supplement* week by week.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In England and Wales infectious diseases were less prevalent than in the preceding week. Acute pneumonia was lower in incidence by 135 cases, measles by 51, diphtheria by 47, scarlet fever by 24. The only rises were 61 for whooping-cough, and 27 for dysentery.

Only very small changes occurred in the local returns of scarlet fever. The largest variations in the incidence of measles were increases of 28 in Suffolk and 23 in London, and a decrease in Durham of 25. A rise in the notifications of whooping-cough was recorded in several counties, including Yorks West Riding 43 more, London 26, Norfolk 26, Warwickshire 25, and Kent 24; the largest fall was Southampton 34. Diphtheria incidence fell in Durham by 17, Northamptonshire by 14, and Glamorgan-shire by 13, and rose in Northumberland by 15.

An outbreak of dysentery involving 38 persons was reported from Peterborough R.D. A further 114 cases were notified in Leicestershire, bringing the total cases of dysentery in this county during the past four weeks to 528. In the three preceding weeks the outbreak was confined to the Melton Mowbray district, but another centre of infection appeared during the week and the returns were Melton Mowbray U.D. 54, Melton and Belvoir R.D. 26, Leicester C.B. 34. The other large returns were Lancashire 58, Yorks West Riding 32, London 20, Northumberland 20, Essex 12, Warwickshire 10, Surrey 10.

Peripheral neuritis has been reported at Rhuddlan, Flintshire, where about 30 persons have been hospitalized with paralysis, mainly in the feet and legs. Other cases have been recorded in the Merseyside district as far apart as Bebington, Port Sunlight, Birkenhead, and Wallasey.

In Scotland the chief feature of the returns was the large increase in dysentery, from 37 to 75; the main centres of infection were Glasgow (20 cases), Lanark County (11), Dundee (11). An increase of 12 in the notifications of cerebrospinal fever was reported from Glasgow. Other infectious diseases were less prevalent, the falls being: measles 51, diphtheria 22, and whooping-cough by 23.

In Eire measles notifications fell by 41, diphtheria by 13, and whooping-cough by 23.

In Northern Ireland the notifications of diphtheria rose by 16 cases to a total of 28, the highest level of recent months. Scarlet fever was higher by 11 cases.

Week Ending January 26

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,420, whooping-cough 1,329, diphtheria 428, measles 907, acute pneumonia 1,450, cerebrospinal fever 76, dysentery 358, paratyphoid 3, typhoid 1. Influenza was responsible for 273 deaths in the great towns, the largest weekly total since the outbreak in the autumn of 1943.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 19.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included), (b) London (administrative county), (c) Scotland, (d) Eire, (e) Northern Ireland. Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London), (b) London (administrative county), (c) The 16 principal towns in Scotland, (d) The 13 principal towns in Eire, (e) The 10 principal towns in Northern Ireland. A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

ANY QUESTIONS?

Masturbation in Children

Q.—How should one tackle the problem of masturbation in children? A working-class mother said of her daughter (aged 7): "She always plays with herself at night. I can't get her out of it." I have met many similar cases. What should one say or do?

A.—To give instructions for a specific case is difficult, for the causes of such a condition are many and variable, and we can suggest only the most common.

Physical.—Apart from any gross physical irritation, a common reason for masturbation in such a child is intestinal toxæmia with acid urine producing enough local irritation to cause the trouble. Attention to the bowels and giving barley-water may assist.

Psychological.—Any child may tend to be auto-erotic: (a) because it has been overstimulated sensuously as a young child; (b) because it has felt unhappy or that it is unloved, and finds solace in this way; (c) because it may find the world of reality too difficult, and therefore tends to return to infantile sensuousness as an escape from reality, and in its masturbation lives in a world of fantasy. It is obvious that in none of these cases is punishment called for: it may correct the habit in case (a), but it will make the child worse if (b) or (c) applies. Nor should the child be threatened, for if it is, and yet cannot help masturbating, it may develop an anxiety neurosis from fear of consequences, with night terrors—a common cause of such fears. Indeed, the child's attention should not be called to the condition at all. On the positive side, love and affection, help and encouragement over its difficulties in life, are important; so is encouragement to work with plasticine, to knit and to make things—that is to say, use of the hands in positive creative work rather than their use for sensuous pleasure alone. The mother should, of course, be told not to believe the old wives' stories about the awful consequences of masturbation, and therefore make the child worse by her anxiety. Masturbation is psychologically undesirable, as it is a signal of emotional disturbance, but not a disaster; more harm can be done by worry, anxiety, and threats than by neglect.

Pills for Sea-sickness

Q.—What is the composition of the U.S. Army's "motion-sickness pill"? Can the formula of this wartime secret now be divulged?

A.—The composition of the U.S. Army's motion-sickness pill does not appear to have been disclosed. It can provisionally be assumed, however, that, as in the case of the corresponding British and German remedies, the essential ingredient is hyoscine, 1/100 gr. (0.65 mg.). Various adjuvants have been tried, such as vitamin B₁, but it is doubtful if they make any material difference.

Marriage and Dysmenorrhœa

Q.—An unmarried girl of 22 complains of severe attacks of dysmenorrhœa. First the pain was severe and mild in rotation, now the pains are irregular in severity. The patient has had a comparatively sedentary occupation in the Forces, but off duty she leads an active outdoor life. When she has visited her fiancé pain has been minimal. I have always understood that dysmenorrhœa tends to disappear after marriage. Is this dependent on the stretching of the tissues after labour, or does it result, as the above case would seem to suggest, from sexual stimulation? Would a hormone preparation help?

A.—The erratic appearance of the pain makes it fairly certain that there is not a local organic cause for it and, as in many cases of dysmenorrhœa, some psychological or environmental factor is most likely to blame. On such a basis several adequate explanations could be put forward, and there seems no need to postulate an underlying endocrine disturbance. Separation from her fiancé with its attendant anxieties and nervous strain, doubts and fears often groundless but natural in lovers, unhappiness for one reason or

another, uncongenial work, etc., all might give this girl dysmenorrhœa, and the intensity of the pain would vary according to her circumstances and state of mind at the time. Pelvic congestion due to roused but ungratified sexual feelings might also play a part. Such factors would cease to operate when the girl met her fiancé and painless menstruation might follow. It is tempting to inquire whether coitus took place when they met. No form of endocrine therapy is likely to help. Early marriage, a settled home life with physical and mental contentment, seems the right answer. Meanwhile, however, regular physical exercise and the full and proper employment of leisure should help.

Dysmenorrhœa does tend to improve with marriage, but more especially with childbearing. The latter has a good effect particularly in cases of spasmodic dysmenorrhœa when the pain is related to uterine contractions (? incoordinate). Pregnancy in itself perhaps plays a part by altering the vascularity, development, and arrangement of the musculature, but the dilatation of the cervix during labour is probably more important in determining co-ordinate muscular action thereafter. As indicated above, marriage acts mainly by ensuring a settled and contented mind after the period of emotional strain associated with "engagement." Other mechanisms may also operate. A full sex life may increase the blood supply to the uterus and minimize ischaemia, which is believed to be a pain-producing factor. Or the practice of regular coitus may reduce the pelvic congestion resulting from sexual stimulation without satisfaction which ends prolonged courtship. It follows that marriage does not always relieve dysmenorrhœa, and under some circumstances it may precipitate it in a girl whose periods have previously been painless. This may happen if the marriage lacks harmony or introduces anxiety of any kind, if there is dyspareunia or failure to achieve sexual satisfaction on the woman's part, etc.

Acne Vulgaris

Q.—An otherwise healthy married woman of 22 has for several years had pimples on her face. Could the underlying cause be some female hormonal imbalance? Recently, during pregnancy, her skin became unusually clear. The pimples, however, returned soon after the pregnancy had ended in an accidental abortion. Would endocrine therapy be of any value?

A.—Acne vulgaris, as described above, requires the operation of at least two complementary factors—the age-endocrine factor and a seborrhoeic make-up. In some cases endocrine therapy has been used with success, but it may still be considered in the experimental stage. For treatment of the skin a 1% sulphur cream is a safe and usually efficient application.

Delayed Resolution after Pneumonia

Q.—Is there any treatment for delayed resolution after acute lobar pneumonia? Is physiotherapy of any use? Is delayed resolution more apt to occur with the use of sulphathiazole as compared with sulphapyridine?

A.—Delayed resolution after acute pneumonia is frequently due to obstruction of the bronchi and to small collections of pus in the pleura, which should be dealt with without delay. That due purely to the failure of the exudate in the alveoli to become liquefied and absorbed is relatively uncommon. If recognized early a further full course of sulphonamides, or penicillin if the organism is penicillin-sensitive, should be given. As soon as the patient's condition permits it breathing exercises designed to promote basal expansion should be started. Short-wave therapy has been recommended and can be tried, but has usually given disappointing results.

There is no real evidence that delayed resolution is more common with the use of sulphathiazole as compared with sulphapyridine if the former is used correctly.

Fatal Dyspnoea in a Child

Q.—A boy of 3 years was brought to hospital in great respiratory distress, which came on suddenly while he was quietly playing a few hours before. He was cyanosed, and the expiratory efforts appeared to be greater than the inspiratory. Clinical examination revealed no helpful feature; the child was afebrile. The chest was normal on x-ray examination. Antidiphtheritic serum was given. Tracheotomy reduced the respiratory rate from 54 to 26. Antispasmodics had no effect. The child died in coma and profound respiratory distress some 48 hours after admission. Necropsy revealed only a congested tracheal mucosa, with some mucus, probably terminal, in the larger bronchi. I am completely at a loss for a diagnosis.

A.—The sudden onset of dyspnoea in a previously healthy child suggests either an allergic reaction of an asthmatic type or inhalation of a foreign body. The asthmatic attack usually passes off fairly quickly, and a foreign body would be revealed at operation or necropsy. The post-mortem finding of mucosal congestion in the trachea and mucus in the bronchioles suggests an infective condition. Laryngeal diphtheria is unlikely—membrane would have been found and the onset would be much less acute. Acute laryngitis with oedema due to infection with *H. influenzae* has been described

in the American literature, and may end-fatally in a few days; blood culture yields a pure growth of the organism. Other pathogens which may be associated with this condition are the haemolytic streptococcus and the pneumococcus. Many pathologists are peculiarly averse to taking material for bacteriological examination at necropsy. If this had been done the cause of the laryngeal obstruction might have been revealed. The absence of fever does not rule out a diagnosis of acute infection if the child was in a collapsed state. The possibility of some chemical poisoning must also be kept in mind, although there does not seem to be anything in the history to suggest this.

Nicotinic Acid in Coronary Disease

Q.—What value can be placed on nicotinic acid in the treatment of coronary disease? Has it any beneficial action beyond that of vasodilatation?

A.—Nicotinic acid has recently been used with a view to causing dilatation of the coronary arteries. Further than that, it probably has no effect on the heart. How far this is of real clinical benefit is somewhat doubtful; reports so far have been rather contradictory. It must be remembered that the nature of the disease in the coronary arteries in some cases precludes much prospect of vasodilatation. Nicotinic acid can be given by injection, but, as the administration must be continuous, and even then the effect is only short-lived, probably the most effective way is to give it by mouth.

Treating Minors for V.D.

Q.—The problem of handling V.D. cases in minors raises difficulties from time to time. Suppose, for example, a girl aged 15 years reporting at a V.D. clinic is found to be leading an immoral life, should the medical officer treat her for V.D. in absolute confidence, or should he, in view of her age, inform the parents (a) of her immoral ways, or (b) if she should default during the contagious stage of the disease? Can the medical officer be held legally responsible for breaking confidence with his patient? Would you adopt a uniform policy in all such cases?

A.—In such a case as that described the medical officer (of a V.D. treatment centre) is torn between two loyalties—one to the patient and the other to the public, including the parents. Strictly according to the terms of his appointment he is not allowed to divulge any information concerning the patient; his best plan is to invoke the help of a lady almoner or a social service worker, who will take the girl in hand and usually be able to persuade her to give permission for her parents to be told, or to return for treatment if she has defaulted. Defaulting nowadays is of less importance from the public health point of view than formerly, since even one injection of penicillin usually rapidly renders the patient non-contagious. Frequently it is possible to discover the name and address of the person by whom the patient was infected, or of person(s) infected by the patient, in which case notification can be made to the appropriate medical officer of health, who will take action under Regulation 33B. Legally, if the medical officer informed the parents he would lay himself open to an action for libel or slander, but in our opinion no court would convict him if he could prove he acted in good faith, without malice, and in the interests of the public health and of the patient. It is quite impossible to recommend a uniform policy in such cases. So much depends on various factors: whether the girl is living at home or not, whether she is a real "bad hat" or just weak, whether she is a prostitute or merely an "enthusiastic amateur." Persuasion and tact will usually be effective, and a lady almoner will often succeed where a medical officer fails.

Gout and Pernicious Anaemia

Q.—May I have advice on a case of pernicious anaemia complicated by gout. The patient is a man of 55 who has been taking liver injections every four weeks or so. In the last few months he has developed gout. Could this attack of gout be due to the liver injections? If so, how should a combination of these two diseases be treated?

A.—The association between pernicious anaemia and gout appears to be too frequent to be explained by mere coincidence. It has been more often noted since the introduction of liver treatment, and particularly since the introduction of parenteral therapy. Injection of liver extract may provoke attacks in two ways. At the beginning of treatment the regeneration of the blood is associated with an increased production of uric acid, which may be a factor in the attack. During maintenance treatment, however, the action is non-specific. In the gouty subject a variety of substances will provoke attacks when injected subcutaneously, including salyrgan, ergotamine tartrate, and vitamin B₁₂. Intramuscular extract of liver must be included in the same category. This can be compared with the effect of trauma in inducing attacks of gout. If in the present patient an exacerbation of the gout always follows within 24 to 48 hours of an injection it might be wise to change to oral therapy. If this is not the case, then parenteral liver therapy should be continued unchanged and the gout should be treated independently with colchicine and the usual ancillary measures.

Chronic Glaucoma

Q.—What, briefly, is the modern view of the aetiology of chronic glaucoma?

A.—Usually chronic glaucoma follows the acute stage, with the proviso that glaucoma simplex may have no recognizable acute period. The causes of the chronic type are, therefore, those of the acute. There is much controversy on the subject; in fact, one of the most recently published textbooks frankly admits that the cause of glaucoma is unknown. In general it may be said that glaucoma is due to an upset in the balance between the production and elimination of the intraocular fluid. This may occur in many ways varying from a restriction of the filtration angle of the anterior chamber to an alteration in the physical composition of the aqueous. In secondary glaucoma the cause is often more apparent—e.g., iritis—and in some respects differs from primary glaucoma.

LETTERS, NOTES, ETC.

The Nation's Health in General Practice

Dr. F. M. SANDFORD (West Wickham) writes: With regard to Dr. Holden's report to the Croydon Council on the health of the nation, it is possible that my observations since my return to practice of two types of illness may be of some interest. I refer to (1) asthma in infancy and (2) spontaneous abortion. Both of these conditions were relatively rare in a large mixed general practice in this neighbourhood prior to 1940; the incidence averaged one per annum. Since my return, although my practice is about half its original size, I have encountered six asthmatic children and four cases of spontaneous abortion in fifteen weeks. I would suggest that in the asthmatic child there is a marked decreased resistance to upper respiratory infections in an already allergic child. In regards spontaneous abortion I must confess that the scientific explanation escapes me in this condition, but I have a vague feeling that there is a nutritional shortage or imbalance which prevents firm implantation of the ovum.

Telling the Patient

Mr. J. H. BADCOCK (Mandeville, Jamaica) writes: With reference to the recent correspondence on this subject an incident which occurred in my practice is worth recording. A man, always nervous about himself, had some gum trouble and was referred to a bacteriologist for examination as to the possible cause. I forgot what the findings were, except that they were not of serious importance. They were duly discussed with the patient, and at his request he was allowed to take away the report giving the names of the various organisms found, sounding doubtless formidable enough to a layman. A day or two later he committed suicide. One cannot be too careful about what one tells a patient and how one tells it.

Weil's Disease

Mr. A. D. GARDNER and **Dr. J. A. H. WYLIE** write from the St. William Dunn School of Pathology, Oxford: We should be greatly obliged if all clinical bacteriologists who have been carrying out the serological diagnosis of Weil's disease would let us know: in many cases they have diagnosed during the years 1940 to 1945, and (if quite easy) the number of sera they have tested for this purpose.

Tribute to a Printer

Mr. F. A. Turner, who worked for us for 26 years, has gone into well-earned retirement, and we are sorry indeed to lose him. I came to our type-setting room with long experience behind him, and on the death of Mr. Brunette, who had succeeded the late Mr. Lapworth, he stepped into the responsible post of head printer (or foreman compositor as it is known in the industry). It was his task to put into practice week by week the typographical reforms carried out at the end of 1936 under Mr. Stanley Morison's guidance. When the whole printing of the *British Medical Journal* was transferred to Messrs. Eyre and Spottiswoode he moved with it but paid regular visits to B.M.A. House. Enemy bombs in May 1941, destroyed the last of Eyre and Spottiswoode's three works and near-Fetter Lane; at a few hours' notice Mr. Turner and his team were at the Temple Press in Clerkenwell, and that week's number came out on time. In July, 1941, our printing was transferred to safer quarters at St. Albans, where Mr. Turner continued to work for the *Journal* in the employ of Messrs. Fisher, Knight and Co. His good craftsmanship and ready resource have never failed. Tribute was paid to his faithful service at last week's Council meeting.

Correction

A slip at the printers' caused the initials of Dr. L. P. Le Questre to be wrongly printed at the head of his article on "Bacteriology of Septic Fingers" in last week's *Journal* at page 163.

PRIMARY ATYPICAL PNEUMONIA

BY

Major A. B. ADAMS, M.B., Ch.B.N.Z. Major J. M. STAVELEY, M.C., M.B., Ch.B.N.Z.
Major G. L. ROLLESTON, M.B., Ch.B.N.Z. Major W. E. HENLEY, D.M.Oxon, M.R.A.C.P.

AND

Col. J. E. CAUGHEY, M.D.N.Z., M.R.C.P.Lond., F.R.A.C.P.

(From the Medical Division of No. 2 N.Z. General Hospital)

Between February and April, 1945, an epidemic of primary atypical pneumonia occurred in British base and training units in the Naples area. During this period approximately 350 cases of primary atypical pneumonia were admitted to a neighbouring British general hospital and 161 to this hospital. Of these 161, 50 unselected consecutive cases were investigated in particular detail. All degrees of severity were represented. There were no deaths. Epidemiologically, it was of interest that the rising incidence of primary atypical pneumonia coincided with the decline of infective hepatitis. Clinical data, serial laboratory investigations, and radiological findings relating to these 50 cases are summarized in this report, which is a preliminary survey of the material collected. In the literature available to us we have been unable to locate any report of the finding of heterophil antibodies in serum from cases of primary atypical pneumonia. For that reason an early report is considered desirable to enable investigators, under research conditions, to repeat the work in subsequent epidemics.
